REVERSIBILITY IN QUEUEING MODELS

MASAKIYO MIYAZAWA
Tokyo University of Science,
Noda, Japan

INTRODUCTION

Stochastic models for queues and their networks are usually described by stochastic processes, in which random events evolve in time. Here, time is continuous or discrete. We can view such evolution in reverse for each stochastic model. A process for this backward evolution is referred to as a *time-reversed process*. It also is called a reversed time process or simply a reversed process. We refer to the original process as a *time-forward process* when it is required to distinguish it from the time-reversed process.

It is often greatly helpful to view a stochastic model from two different time directions. In particular, if some property is invariant under change of the time directions, that is, under time reversal, then we may better understand that property. A *concept of reversibility* is invented for this invariance.

A comprehensive discussion on reversibility in queueing networks and related models is presented in the book by Kelly [1]. The reversibility used is in the sense that the time-reversed process is stochastically identical to the time-forward process, but there are many discussions about stochastic models with time reversal having the same modeling features. In this article, we give a unified view to them, using a broader concept of reversibility. We first consider some examples.

1. A *stationary Markov process* (continuous- or discrete-time) is again a stationary Markov process under time reversal. This is detailed in the section titled “Markov Chain and Its Time Reversal.” In this case, the property

that transition probabilities from a given state are independent of past history and the present time, called the time homogeneous *Markov property*, is reversible for a stationary Markov processes.

2. A *random walk* is a discrete-time process with independent increments, and again a random walk under time reversal; that is, the time-reversed process also has independent increments. Hence, the independent increment property is reversible for a random walk. A random walk is a special case of a discrete-time Markov process, but it does not have a stationary distribution.
3. A *queueing model* is a system to transform an arrival stream to a departure stream. If the queueing model can be reversed in time, the roles of arrival and departure streams are exchanged, but the input–output structure may be considered to be unchanged. Thus, the stream structure is reversible for the queueing model. It is notable that a stochastic process for this model does not need to have a stationary distribution. We propose a self-reacting system for this type of models in the section titled “Self-Reacting System and Balanced Departure.”
4. A *birth-and-death process* is a continuous-time Markov process taking nonnegative integers that go up or down by 1. This process is typically used to represent population dynamics of living things. It is also used to model a queueing system called a *Markovian queue* (see section titled “Queue and Reacting System”).

These examples may be too general or too specific to be of some use, but they suggest that there may be different levels of reversibility depending on characteristics of interest and on the class of stochastic processes (or models). In particular, (4) is a

special case of (1) if it has a stationary distribution. As we will see later, this Markov chain with a stationary distribution is reversible in time, that is, the time-reversed Markov chain is stochastically identical to the time-forward process. Thus, (1) and (4) are two extremes concerning the time-reversed processes that have stationary distributions.

How can we define reversibility of a stochastic process for a queueing model? Obviously, we need a time-reversed dynamics. How can we construct it? Is the stationary distribution required for this? The answer is “no” because of examples (2) and (3). To make the problems concrete, we consider discrete- and continuous-time Markov processes with countable state spaces, which are referred to as *discrete- and continuous-time Markov chains*, respectively, because they are widely used in queueing and their network applications.

When we are interested in the stationary distributions of the Markov chains, we have to verify or assume their existence. In this case, there should be a useful notion of reversibility between extreme cases such as (1) and (4). However, structural properties such as arrivals and departures may not depend on whether or not underlying Markov chains for them have stationary distributions. We aim to devise such reversibility, which is discussed in the section titled “Local Balance and Reversibility in Structure” under *reversibility in structure*. We show how this concept arises in queueing models and their networks and how it is useful to obtain the stationary distributions in a unified way in the subsequent sections up to the section titled “Queueing Network and Product Form.” Reversibility in structure is discussed for other types of Markov processes in the section titled “Other Stochastic Processes” and some remarks for further study are given in the section titled “Concluding Remarks.”

Before we start these discussions, we recall basic facts about Markov chains and their time reversals in the section titled “Markov Chain and Its Time Reversal.” The reader who is familiar with those topics may skip this section. However, it may be noted that we define a transition rate function in a

slightly extended manner. Thus, we recommend that the reader check this definition.

MARKOV CHAIN AND ITS TIME REVERSAL

In this section, we construct time-reversed processes for discrete- and continuous-time Markov chains. We first consider the discrete-time case because it is simpler than the continuous-time case, however, the arguments are similar. A discrete-time stochastic process $\{X_n; n = 0, 1, \dots\}$ with S is called a Markov chain if, for any $n \in \mathbb{Z}_+ \equiv \{0, 1, 2, \dots\}$ and any $i, j, i_0, \dots, i_{n-1} \in S$,

$$\begin{aligned} \mathbb{P}(X_{n+1} = j | X_0 = i_0, X_1 = i_1, \dots, X_{n-1} \\ = i_{n-1}, X_n = i) = \mathbb{P}(X_{n+1} = j | X_n = i). \end{aligned}$$

If the right-hand side is independent of n , then it is said to have a *time-homogeneous transition*, which is denoted by p_{ij} . That is,

$$p_{ij} = \mathbb{P}(X_{n+1} = j | X_n = i), \quad i, j \in S.$$

This p_{ij} is called a *transition probability* from state i to state j . Throughout this article, we always assume Markov chains to be time homogeneous. To exclude trivial exceptions, we further assume that there is a path from i to j for each $i, j \in S$, that is, there are states $i_1, i_2, \dots, i_{n-1} \in S$ for some $n \geq 1$ such that

$$p_{ii_1} p_{i_1 i_2} \times \dots \times p_{i_{n-2} i_{n-1}} p_{i_{n-1} j} > 0. \quad (1)$$

This condition means that any state is commutative with any other state; this is known as *irreducibility*.

If a probability distribution $\pi \equiv \{\pi(i)\}$ on S , that is, $\pi(i) \geq 0$ for all i such that $\sum_{i \in S} \pi(i) = 1$, satisfies

$$\pi(j) = \sum_{i \in S} \pi(i) p_{ij}, \quad j \in S, \quad (2)$$

then π is called a *stationary distribution* of the Markov chain $\{X_n\}$. Note that, $\pi(j) > 0$ for all $j \in S$ by the irreducibility. If the Markov chain $\{X_n\}$ has a stationary distribution π and if X_0 is subject to this π , then X_n has the

distribution π for each $n \geq 1$. Define the time-shifted process $\{X_n^{(-\ell)}; n = -\ell, -(\ell-1), \dots\}$ by

$$X_n^{(-\ell)} = X_{n+\ell}, \quad n = -\ell, -(\ell-1), \dots$$

Then, $\{X_n^{(-\ell)}; n \geq m\}$ for each $m \geq -\ell$ has the same joint distribution as $\{X_n; n \geq 0\}$ as long as X_0 has the stationary distribution π , and therefore, by letting $\ell \rightarrow \infty$, the Markov chain $\{X_n^{(-\infty)}; n \in \mathbb{Z}\}$ is well defined, where $\mathbb{Z}$ is the set of all integers. Thus, we can consider the Markov chain $\{X_n\}$ to be a process starting from $-\infty$. This allows us to define a time-reversed process $\{\tilde{X}_n\}$ by

$$\tilde{X}_n = X_{-n}, \quad n \in \mathbb{Z}. \quad (3)$$

Since $\mathbb{P}(X_{-(n+1)} = j) = \pi(j)$, we have

$$\begin{aligned} \mathbb{P}(\tilde{X}_0 = i_0, \tilde{X}_1 = i_1, \dots, \tilde{X}_n = i, \tilde{X}_{n+1} = j) \\ &= \mathbb{P}(X_0 = i_0, X_{-1} = i_1, \dots, X_{-n} = i, X_{-(n+1)} = j) \\ &= \mathbb{P}(X_{-(n+1)} = j) \mathbb{P}(X_0 = i_0, X_{-1} = i_1, \dots, \\ &\quad X_{-(n-1)} = i | X_{-(n+1)} = j) \\ &= \pi(j) p_{ji} p_{ii_{n-1}} \times \dots \times p_{i_1 i_0}, \end{aligned}$$

and therefore

$$\begin{aligned} \mathbb{P}(\tilde{X}_{n+1} = j | \tilde{X}_0 = i_0, \tilde{X}_1 = i_1, \dots, \tilde{X}_n = i) \\ &= \frac{\mathbb{P}(\tilde{X}_0 = i_0, \tilde{X}_1 = i_1, \dots, \tilde{X}_n = i, \tilde{X}_{n+1} = j)}{\mathbb{P}(\tilde{X}_0 = i_0, \tilde{X}_1 = i_1, \dots, \tilde{X}_n = i)} \\ &= \frac{\pi(j) p_{ji} p_{ii_{n-1}} \times \dots \times p_{i_1 i_0}}{\pi(i) p_{ii_{n-1}} \times \dots \times p_{i_1 i_0}} \\ &= \frac{\pi(j) p_{ji}}{\pi(i)} = \mathbb{P}(\tilde{X}_{n+1} = j | \tilde{X}_n = i). \end{aligned}$$

Hence, the time-reversed process $\{\tilde{X}_n\}$ is also a Markov chain with transition probability $\tilde{p}_{ij}$ given by

$$\tilde{p}_{ij} = \frac{\pi(j)}{\pi(i)} p_{ji}, \quad i, j \in S. \quad (4)$$

We have defined the time-reversed process $\{\tilde{X}_n\}$ by Equation 3, but we also can define it as a Markov chain with transition probabilities $\{\tilde{p}_{ij}\}$ of Equation 4. Furthermore, for the latter definition, it is not necessary for $\{\pi(i)\}$ to be a probability distribution, but $0 <$

$\pi(i) < \infty$ for all $i \in S$ satisfying Equation 2 is sufficient. This $\{\pi(i)\}$ is called a *stationary measure*. This also explains why a random walk can be reversed in time because $\pi(i) = a$ for any constant $a > 0$ is its stationary measure. We refer to the measure π to define $\tilde{p}$ of Equation 4 as a reference measure (see Definition 2 and Section 3 of [2] for related topics).

It is notable that we can use a reference measure other than a stationary measure. For example, we can consider a time-reversed process $\{X_{n_0-n}; 0 \leq n \leq n_0\}$ starting at $X_{n_0} = i_0$ for fixed time $n_0 > 0$ and state $i_0 \in S$. In this case, the reference measure is concentrated on i_0 . It can be shown that this process is again a Markov chain, but does not have time-homogeneous transitions. Thus, it is different from $\{\tilde{X}_n\}$. As a reference measure, a stationary distribution (or measure) has the excellent feature that the transition probabilities have a simple form.

Thus, the choice of a reference measure is crucial for the time-reversed process. Throughout this article, we take a stationary distribution (a stationary measure in a few instances) as a reference measure for a time-reversed process. However, this does not mean that we also take it for reversibility in structure, which will be considered in the section titled ‘‘Local Balance and Reversibility in Structure,’’ because the structural property should be independent of the existence of the stationary distribution.

We next consider a continuous-time Markov chain, for which irreducibility is assumed. This is quite easy because most arguments are parallel to those of a discrete-time Markov chain.

A stochastic process $\{X(t)\}$ with state space S is called a *Markov chain* if, for each $n \in \mathbb{Z}_+$, any $s > 0$, any $0 < t_1 < \dots < t_n < s$ and any $i, j, i_0, \dots, i_n \in S$,

$$\begin{aligned} \mathbb{P}(X(s+t) = j | X(0) = i_0, X(t_1) = i_1, \dots, X(t_n) \\ &= i_n, X(s) = i) \\ &= \mathbb{P}(X(s+t) = j | X(s) = i). \end{aligned}$$

We denote the right-hand side of this equation by $p_{ij}(t)$ if it is independent of s , which we always assume. We also assume

that, for each $i, j \in S$, there exists $t > 0$ such that $p_{ij}(t) > 0$, which is called *irreducibility*.

Then, it is known that there exist $a(i) \geq 0$ and $q(i, j) \geq 0$ such that

$$\lim_{h \downarrow 0} \frac{1}{h} p_{ij}(h) = q(i, j), \quad i \neq j, i, j \in S,$$

$$\lim_{h \downarrow 0} \frac{1}{h} (p_{ii}(h) - 1) = -a(i), \quad i \in S.$$

In words, $a(i)$ is a rate going out from state i , and $q(i, j)$ is a transition rate from i to j under the condition that the transition occurs. Throughout this article, we assume that $a(i)$ is finite for all $i \in S$. It is not hard to see that

$$a(i) = \sum_{j \neq i, j \in S} q(i, j), \quad i \in S,$$

and the Markov chain $\{X(t)\}$ is determined by $\{q(i, j); i, j \in S\}$. For $X(t)$ to be well defined for all $t \geq 0$, a certain regularity condition is required (e.g., see Section 2.2 of [3]). However, it is always satisfied in queueing applications.

This continuous-time Markov chain is slightly extended by adding dummy transitions by letting $q(i, i) \geq 0$. In this case, we redefine $a(i)$ as

$$a(i) = \sum_{j \in S} q(i, j), \quad i \in S.$$

In standard text books (e.g., Ref. 3), $q(i, i)$ is usually defined as $q(i, i) = -a(i)$. Thus, it is notable that our $q(i, i)$ is different from these. As a stochastic process, $q(i, i) > 0$ is not meaningful because it does not change the state. However, it is important for describing a queueing model because it enables to correctly count arriving customers who cannot enter a system. We refer to q as a *transition rate function*.

Since the Markov chain is irreducible, its stationary distribution π is uniquely determined by

$$a(j)\pi(j) = \sum_{i \in S} \pi(i)q(i, j), \quad j \in S. \quad (5)$$

This equation is slightly different from Equation 2 of the discrete-time Markov chain.

This is because the transition rate function $\{q(i, j); j \in S\}$ is not a probability distribution for the given i . Assume that the Markov chain has the stationary distribution π , then all arguments for the discrete-time Markov chain are valid for the continuous-time Markov chain if we replace p_{ij} by $q(i, j)$ and make small modifications as in Equation 5. Denote the time-reversed Markov chain by $\{\tilde{X}(t)\}$, then, similar to Equation 4, its transition rate function $\tilde{q}$ is given by

$$\tilde{q}(i, j) = \frac{\pi(j)}{\pi(i)} q(j, i), \quad i, j \in S. \quad (6)$$

From Equations 6 and 5, we immediately have the next fact.

Lemma 1. A probability distribution π on S is the stationary distribution of the Markov chain with transition rate function q if and only if there exists a nonnegative function $\tilde{q}$ on S such that

$$\pi(i)\tilde{q}(i, j) = \pi(j)q(j, i), \quad i, j \in S, \quad (7)$$

$$\sum_{j \in S} \tilde{q}(i, j) = \sum_{j \in S} q(i, j), \quad i \in S. \quad (8)$$

A message from this lemma is that the stationary distribution can be found if we can guess $\tilde{q}$ from the time-reversed model. This idea is extensively used in the book [1], and Lemma 1 is called *Kelly's lemma* (e.g., see Ref. 4).

LOCAL BALANCE AND REVERSIBILITY IN STRUCTURE

From now on, we only consider the continuous-time Markov chain $\{X(t)\}$ with state space S and transition probabilities $\{X(t)\}$ because the corresponding results for a discrete-time Markov chain are similarly obtained. We also change the notation for state from $i, j \in S$ to $x, x' \in S$ for convenience of our discussions.

We aim to define reversibility in structure for this Markov chain. For this, we first consider the strongest case that the Markov chain $\{X(t)\}$ itself is reversible. Assume that

it has the stationary measure π , and define the time-reversed Markov chain $\{\tilde{X}(t)\}$ with transition rate functions $\tilde{q}$. Then, $\{X(t)\}$ is stochastically identical to its time-reversed process $\{\tilde{X}(t)\}$ if and only if

$$q(x, x') = \tilde{q}(x', x), \quad x, x' \in S.$$

From Equation 6, this condition is equivalent to

$$\pi(x)q(x, x') = \pi(x')q(x', x), \quad x, x' \in S. \quad (9)$$

This Markov chain is said to be *reversible*. It is notable that Equation 9 yields, for fixed x and the sequence of the states $x, x_1, \dots, x_{n-1}, x' \in S$,

$$\pi(x') = \pi(x) \frac{q(x, x_1)q(x_1, x_2) \times \dots \times q(x_{n-1}, x')}{q(x', x_{n-1}) \times \dots \times q(x_2, x_1)q(x_1, x')}.$$

as long as the denominator in the right-hand side is positive. Hence, we have the stationary distribution π if $\sum_{x \in S} \pi(x) < \infty$. Otherwise, this π is a stationary measure. Thus, the reversibility enables us to obtain the stationary distribution.

A typical example of a reversible Markov chain is a *birth-and-death process*, which is defined in (4) of the section titled “Introduction.” Recall that its state space $S = \mathbb{Z}_+$, and the transition probability $q(x, x') > 0$ for $x, x' \in S$ if and only if $x' = x + 1, x' = x - 1 \geq 0$ or $x = x' = 0$. For this Markov chain, let

$$\begin{aligned} \pi(x) &= \pi(0) \frac{q(0, 1)}{q(x, x-1)} \times \frac{q(1, 2)}{q(x-1, x-2)} \\ &\quad \times \dots \times \frac{q(x-1, x)}{q(1, 0)}, \quad x \in S, \end{aligned} \quad (10)$$

then Equation 9 is satisfied. Hence, the birth-and-death process is reversible.

However, a Markov chain for a queueing model may not be reversible. In particular, this reversibility is too strong for queueing networks. Motivated by this, the following notion has been studied, which is weaker than reversibility.

Definition 1. [Local balance]. Assume that the Markov chain $\{X(t)\}$ with transition rate function q has a stationary distribution

π , and let $\tilde{q}$ be the transition rate function of its time-reversed process. Let W be a set of disjoint subsets of $S \times S$. If the Markov chain satisfies

$$\sum_{(x, x') \in C} \pi(x)q(x, x') = \sum_{(x, x') \in C} \pi(x)\tilde{q}(x, x'), \quad C \in W, \quad (11)$$

or equivalently,

$$\sum_{(x, x') \in C} \pi(x)q(x, x') = \sum_{(x, x') \in C} \pi(x')q(x', x), \quad C \in W, \quad (12)$$

then transition rate function q is said to be *locally balanced* with respect to W .

We can weaken the local balance by using the so-called test functions. Let $\mathcal{M}_+(S \times S)$ be the set of all nonnegative-valued functions on $S \times S$. For a subset $\mathcal{G}$ of $\mathcal{M}_+(S \times S)$, q is said to be *locally balanced* in test functions of $\mathcal{G}$ if

$$\begin{aligned} &\sum_{x, x' \in S} \pi(x)q(x, x')f(x, x') \\ &= \sum_{x, x' \in S} \pi(x')q(x', x)f(x, x'), \quad f \in \mathcal{G}. \end{aligned} \quad (13)$$

Let $\mathcal{G}$ be the set of indicator functions $1((x, x') \in C)$ for $C \in W$ of definition 1, where $1(\cdot)$ is the function of the statement “.” such that it equals 1 if the statement is true and 0 otherwise, then Equation 13 is equivalent to Equation 12. Hence, Equation 13 certainly generalizes Equation 12.

However, the local balance in test functions still has limitations. A problem is that transition rate functions q and $\tilde{q}$ are directly related through balance equations. This limits flexibility of $\tilde{q}$ to be chosen. Furthermore, it also requires that q has a stationary distribution. Instead of balance equations and stationary distribution, we use a set of pairs of transition rate functions q and measure σ on S to support q for a weaker sense of reversibility, where σ is said to be a measure to support q or a *supporting measure* of q if $\sigma(x) \geq 0$ for all $x \in S$, and, for each $x \in S$, $\sigma(x) > 0$ if $q(x', x) > 0$ for some $x' \in S$.

We denote the sets of all measures on S and of all supporting measures of q by $M(S)$ and $M_{\text{sup}}(q)$, respectively.

For $\sigma \in M(S)$, let $\mathcal{T}(\sigma)$ be the set of all transition rate functions on $S \times S$ which are supported by σ , and let

$$\mathcal{T} = \cup_{\sigma \in M(S)} \{(q, \sigma); q \in \mathcal{T}(\sigma)\}.$$

That is, $\mathcal{T}$ is the set of all pairs (q, σ) of transition rate function q and measure $\sigma \in M_{\text{sup}}(q)$. Note that $\sum_{x' \in S} q(x, x') < \infty$ for all $x \in S$ is always assumed, but σ is not necessarily the stationary distribution of q . Furthermore, a Markov chain with transition rate function q may not be irreducible.

Definition 2. [Reversible in structure]. A subset $\mathcal{Q}$ of $\mathcal{T}$ is said to be reversible in structure if $(\tilde{q}, \sigma) \in \mathcal{Q}$ for each $(q, \sigma) \in \mathcal{Q}$, where

$$\tilde{q}(x, x') = \begin{cases} \frac{\sigma(x')}{\sigma(x)} q(x', x), & \sigma(x) > 0, x, x' \in S, \\ 0 & \sigma(x) = 0, x, x' \in S. \end{cases}$$

This σ is called a *reference measure* to get $\tilde{q}$ from q . In particular, a Markov chain with transition rate function q is said to be *reversible in structure* with respect to $\mathcal{Q}$ if there is a $\sigma \in M_{\text{sup}}(q)$ such that $(q, \sigma) \in \mathcal{Q}$ implies $(\tilde{q}, \sigma) \in \mathcal{Q}$.

Remark 1. (a) For $\mathcal{Q} \subset \mathcal{T}$ and $\sigma \in M(S)$, let $\mathcal{Q}(\sigma) = \{q \in \mathcal{T}(\sigma); (q, \sigma) \in \mathcal{Q}\}$, then we can write the condition $(q, \sigma) \in \mathcal{Q}$ as $q \in \mathcal{Q}(\sigma)$. The latter is convenient when σ is specified. This is often the case when σ is the stationary distribution π .

(b) For the stationary distribution π of q , $q \in \mathcal{T}(\pi)$, and π is also the stationary distribution of $\tilde{q}$. However, the reversibility in structure does not require σ to be a stationary distribution. In fact, the notion of reversibility in structure is independent of its existence.

Note that $\tilde{\tilde{q}} = q$ for $(q, \sigma) \in \mathcal{Q}$. Hence, q is reversible in structure concerning $\mathcal{Q}$ if and only if $\tilde{q}$ is also so. The structure reversibility obviously includes the local balance in test functions with respect to $\mathcal{G}$. To see this, we

only need to define $\mathcal{Q}$ as the set of (q, π) such that Equation 13 holds for all $g \in \mathcal{G}$ for the stationary distribution π of q . However, $\mathcal{Q}$ of Definition 2 may be still too strong for queueing applications.

Because we are interested in queueing models, we have arrivals and departures to a system, and their roles are exchanged under time reversal. This suggests partially decomposing q into a family of transition rate functions q_u for $u \in U$, where U is a finite set, in such a way that

$$\sum_{u \in U} q_u(x, x') \leq q(x, x'), \quad x, x' \in S, \quad (14)$$

and to define a one-to-one mapping Γ from U to itself such that $\Gamma(\Gamma(u)) = u$. This Γ is said to be a *reflective permutation* on U . We refer to $\{q_u; u \in U\}$ satisfying Equation 14 as a subtransition family of q .

For example, if u represents arrivals, that is, q_u is the transition rate function for arrivals, then $\Gamma(u)$ may be considered to represent departures. Since arrivals are changed to departures under time reversal, we define the transition rate function $\tilde{q}_{\Gamma(u)}$ for $u \in U$ and supporting measure $\sigma \in M_{\text{sup}}(q)$ by

$$\tilde{q}_{\Gamma(u)}(x, x') = \begin{cases} \frac{\sigma(x')}{\sigma(x)} q_u(x', x), & \sigma(x) > 0, \\ & x, x' \in S, \\ 0 & \sigma(x) = 0, x, x' \in S, \end{cases} \quad (15)$$

that is, $\tilde{q}_{\Gamma(u)}$ is obtained from q_u by the reference measure σ . We may consider $\tilde{q}_{\Gamma(u)}$ to be the transition rate function for departures under time reversal with respect to σ . Note that Equation 15 can be used to define $\tilde{q}_u$ if we use $\Gamma^{-1}(u)$ instead of u . These facts motivate us to define the following reversibility in structure.

Definition 3. [Γ -reversible in structure]. For a finite set U and a reflective permutation Γ on U , let $\mathcal{Q}_u$ be a subset of $\mathcal{T}$ for $u \in U$, then $\{\mathcal{Q}_u; u \in U\}$ is said to be Γ -reversible in structure if, for each $\sigma \in M(S)$,

$$q_u \in \mathcal{Q}_u(\sigma) \text{ implies } \tilde{q}_{\Gamma(u)} \in \mathcal{Q}_{\Gamma(u)}(\sigma) \text{ for all } u \in U, \quad (16)$$

where $\mathcal{Q}_u(\sigma) = \{q \in \mathcal{T}(\sigma); (q, \sigma) \in \mathcal{Q}_u\}$ and $\tilde{q}_{\Gamma(u)}$ is defined by Equation 15. In particular, a Markov chain which has transition rate function q and sub-transition family $\{q_u; u \in U\}$ is said to be Γ -reversible in structure with respect to $\{\mathcal{Q}_u; u \in U\}$ if there is a $\sigma \in M_{\text{sup}}(q)$ for which Equation 16 holds. Furthermore, if $\sigma \in M_{\text{sup}}(q)$ is specified, then the Markov chain is said to be Γ -reversible in structure with respect to $\{\mathcal{Q}_u(\sigma); u \in U\}$ if Equation 16 holds.

Remark 2. The Γ -reversibility in structure of $\{\mathcal{Q}_u; u \in U\}$ is a class property for a subset of $\mathcal{T}$, while the Γ -reversibility in structure of a Markov chain with q and $\{q_u; u \in U\}$ is defined for a Markov chain. For the latter, $\{\mathcal{Q}_u; u \in U\}$ itself is not necessarily Γ -reversible in structure. However, the Γ -reversibility in structure of $\{\mathcal{Q}_u; u \in U\}$ is convenient to construct a class of models satisfying such reversibility.

We restate the definition of Γ -reversibility in structure in a convenient form for applications.

Lemma 2. Let Γ be a reflective permutation on a finite set U . Then, $\{\mathcal{Q}_u; u \in U\}$ is Γ -reversible in structure if and only if, for each $\sigma \in M(S)$,

$$\mathcal{Q}_{\Gamma(u)}(\sigma) = \{q_{\Gamma(u)} \in \mathcal{T}(\sigma); \tilde{q}_u \in \mathcal{Q}_u(\sigma)\}, u \in U. \quad (17)$$

Proof. Assume that $\{\mathcal{Q}_u; u \in U\}$ is Γ -reversible in structure. Then, for each $\sigma \in M(S)$, $q_{\Gamma(u)} \in \mathcal{Q}_{\Gamma(u)}(\sigma)$ implies $\tilde{q}_{\Gamma^2(u)} \in \mathcal{Q}_{\Gamma^2(u)}(\sigma)$, which is identical to $\tilde{q}_u \in \mathcal{Q}_u(\sigma)$ because $\Gamma^2(u) = u$. Similarly, $\tilde{q}_u \in \mathcal{Q}_u(\sigma)$ implies $\tilde{q}_{\Gamma(u)} \in \mathcal{Q}_{\Gamma(u)}(\sigma)$, which is identical to $q_{\Gamma(u)} \in \mathcal{Q}_{\Gamma(u)}(\sigma)$. Hence, we have Equation 17. Conversely, Equation 17 and $\sigma \in M(S)$ imply that $\tilde{q}_u \in \mathcal{Q}_u(\sigma)$ leads $\tilde{q}_{\Gamma(u)} \in \mathcal{Q}_{\Gamma(u)}(\sigma)$. Because $\tilde{q}_u = q_u$, $\{\mathcal{Q}_u; u \in U\}$ is Γ -reversible in structure.

We will show how Γ -reversibility in structure and Lemma 2 work for queueing

and their network models in the following sections. In the rest of this section, we briefly discuss a Poisson process that is frequently used in queueing applications as a counting process of customers. We are interested in how it arises in a Markov chain describing a queueing model and how it is connected to structure reversibility.

Definition 4. [Poisson process]. A counting process $N(t)$ is called a *Poisson process* with rate $\lambda > 0$ if it satisfies the following conditions.

- (a1) It has independent increments, that is, for any $n \geq 2$ and any time sequence $t_0 \equiv 0 < t_1 < t_2 < \dots < t_n$, the increments $N(t_\ell) - N(t_{\ell-1})$, $\ell = 1, 2, \dots, n$, are independent.
- (a2) It has stationary increments, that is, for any $s, t > 0$, the distribution of $N(s+t) - N(s)$ is independent of s .
- (a3) It is simple, that is, the increments $N(t) - N(t-)$ at time t is 0 or 1.
- (a4) $\lambda \equiv \mathbb{E}(N(1)) < \infty$.

It is not hard to see that this definition is equivalent to stating that the interoccurrence times for counting are independent and identically distributed subject to the exponential distribution with mean $1/\lambda$.

We note here two important facts related to reversibility. Let q be the transition rate function of the continuous-time Markov chain with a stationary distribution π such that $\pi(x) > 0$ for all $x \in S$. Let q_* be a transition rate function satisfying

$$q_*(x, x') \leq q(x, x'), \quad x, x' \in S. \quad (18)$$

Let $N_*(t)$ be the number of transitions of this Markov chain in the time interval $(0, t]$ generated by q_* . N_* is called a *counting process* of q_* .

Lemma 3. The counting process N_* is the Poisson process with rate $\lambda > 0$ whose occurrences are independent of the state of Markov

chain just before their counting instants if and only if

$$\sum_{x' \in S} q_*(x, x') = \lambda, \quad x \in S. \quad (19)$$

Lemma 3 easily follows from the following facts. The sojourn time at a given state of the Markov chain has an exponential distribution, the interoccurrence times of N_* are exponentially distributed, and mutually independent by the Markov property (see Ref. 4 for a complete proof).

For these q_* and π , recalling that $\pi(x) > 0$ for all $x \in S$, define $\tilde{q}_*$ as

$$\tilde{q}_*(x, x') = \frac{\pi(x')}{\pi(x)} q_*(x', x), \quad x, x' \in S$$

and let $\tilde{N}_*$ be the point process generated by $\tilde{q}_*$. A question is when $\tilde{N}_*$ is a Poisson process with rate λ . This is equivalent for $\tilde{q}_*$ to satisfy Equation 19 instead of q_* , namely,

$$\sum_{x' \in S} \pi(x') \tilde{q}_*(x', x) = \pi(x) \lambda, \quad x \in S. \quad (20)$$

In particular, if $q_* = q$, then Equation 20 automatically holds. This is intuitively clear because $\tilde{N}_*$ is the time-reversed process of N_* under π and a Poisson process is unchanged by time reversal. However, if $q_* \neq q$, then we do need the condition (Eq. 20).

We also can answer this question in terms of reversibility in structure. For this, let q be a transition rate function which has a stationary distribution π , and define $\mathcal{Q}(\pi)$ as

$$\mathcal{Q}(\pi) = \left\{ g \in \mathcal{T}(\pi); \exists c > 0, \right. \\ \left. \sum_{x' \in S} g(x, x') = c, \forall x \in S, g \leq q \right\},$$

where $g \leq q$ means $g(x, x') \leq q(x', x)$ for $x, x' \in S$. Define $\tilde{g}$ as $\tilde{g}(x, x') = \frac{\pi(x')}{\pi(x)} g(x', x)$. Then, the condition that $\tilde{q}_* \in \mathcal{Q}(\pi)$ for $q_* \in \mathcal{Q}(\pi)$ is equivalent to Equation 20. Thus, we have the following result.

Lemma 4. Assume that the Markov chain $\{X(t)\}$ has a stationary distribution π . For each $q_* \in \mathcal{Q}(\pi)$, the counting process $\tilde{N}_*$ generated by $\tilde{q}_*$ is a Poisson process with rate $\lambda > 0$ whose occurrences are independent of the state of Markov chain just after their counting instants if and only if q_* is reversible in structure with respect to $\mathcal{Q}(\pi)$.

QUEUE AND REACTING SYSTEM

We now describe queueing models by a continuous-time Markov chain. As a simplistic example, we first consider a single-server queue. Assume that customers arrive according to the Poisson process with rate $\lambda > 0$, customers are served in the manner of first-come and first-served with independently and exponentially distributed service times with mean $1/\mu$ ($\mu > 0$), which are also independent of the arrival process. This model is called an $M/M/1$ queue.

Let $X(t)$ be the number of customers at time t of the $M/M/1$ queue. Since the remaining times to the next arrivals and to the service completions of a customer being served are independent and subject to exponential distributions, $X(t)$ is a continuous-time Markov chain with state space $S = \{0, 1, \dots\}$, and its transition rate function q is given by

$$q(x, x') = \begin{cases} \lambda, & x' = x + 1, \\ \mu, & x' = x - 1 \geq 0, \\ 0, & \text{otherwise,} \end{cases} \quad x, x' \in S.$$

Hence, $\{X(t)\}$ is a special case of a birth-and-death process, and therefore reversible if it has a stationary distribution. From Equation 10, the stationary measure π is given by

$$\pi(x) = \pi(0) \rho^x, \quad x \in S,$$

where $\rho = \lambda/\mu$, and satisfies (Eq. 9). Hence, the stationary distribution exists if and only if $\rho < 1$.

The $M/M/1$ queue is a simple model, but it has key ingredients of reversibility. For

this, we introduce transition rate functions for arrivals and departures. Let

$$\begin{aligned} q_a(x, x') &= \lambda 1(x' = x + 1), \\ q_d(x, x') &= \lambda 1(x' = x - 1 \geq 0). \end{aligned}$$

Then,

$$\sum_{x' \in S} q_a(x, x') = \lambda, \quad x \in S, \quad (21)$$

$$\sum_{x' \in S} \pi(x') q_d(x', x) = \pi(x) \lambda, \quad x \in S. \quad (22)$$

Hence, by Lemmas 3 and 4, both N_a and N_d are Poisson processes with the same rate λ . Also, by these lemmas, N_a is independent of the past history of the Markov chain while N_d is independent of its future history. These facts are also valid for the $M/M/s$ queue that increases the number of servers in the $M/M/1$ queue from one to s as the Markov chain for the queue is also a birth-and-death process. These facts are known as *Burke's theorem* [5].

We now closely look at the $M/M/1$ queue and Burke's theorem; we can see that Poisson arrivals and Poisson departures occur as long as Equations 21 and 22 are satisfied, and it may not be necessary for the Markov chain $\{X(t)\}$ to be a birth-and-death process. In this situation, we need to have a larger state space S and to suitably choose $(q_a, \pi) \in \mathcal{T}$ for arrival and $(q_d, \pi) \in \mathcal{T}$ for departures, where π is the stationary distribution of $\{X(t)\}$. Another issue is that we may not be able to define the arrival process *a priori* because it may be a superposition of departure processes of other queues in network applications.

For resolving these issues, we separate the exogenous arrival process from the queueing system, and introduce the following formulation according to [4]. Let S be the state space of the queueing system removing the arrival process. Assume the following dynamics.

- (b1) A customer under state x departs with rate $q_d(x, x')$, changing x to x' .
- (b2) An arriving customer who finds state $x \in S$ changes it to $x' \in S$ with probability $p_a(x, x')$, where $\sum_{x' \in S} p_a(x, x') = 1$ for each $x \in S$.

- (b3) The system state x changes to x' with rate $q_1(x, x')$ without departure. This state transition is said to be *internal*.

This model is fairly general as a queueing system, but has nothing to do with a customer arrival process. We refer to this model as a *reacting system*.

We feed Poisson arrivals with rate $\alpha > 0$ to this reacting system, and define transition rate functions by

$$\begin{aligned} q(x, x') &= \alpha p_a(x, x') + q_d(x, x') \\ &\quad + q_i(x, x'), \quad x, x' \in S. \end{aligned} \quad (23)$$

Denote the Markov chain with transition rate function q by $\{X(t)\}$. This Markov chain represents the dynamics given by (b1), (b2), and (b3), where all actions except for (b1) occur with exponentially distributed interoccurrence times.

Assume that this Markov chain has a stationary distribution π . Then, the transition rate function $\tilde{q}$ of the time-reversed Markov chain $\{\tilde{X}(t)\}$ is given by Equation 6. A question is under what conditions $\{\tilde{X}(t)\}$ represents a reacting system with Poisson arrivals.

This problem can be stated using Γ -reversibility in structure. For this, define q_a as

$$q_a(x, x') = \alpha p_a(x, x'), \quad x, x' \in S,$$

and let $U = \{a, d\}$ and let Γ be the permutation on U such that $\Gamma(a) = d$ and $\Gamma(d) = a$. This Γ is clearly reflective. Define $\mathcal{Q}_a(\sigma)$ for $\sigma \in M(S)$ as

$$\begin{aligned} \mathcal{Q}_a(\sigma) &= \left\{ g_a \in \mathcal{T}(\sigma); \exists c > 0, \sum_{x' \in S} g_a(x, x') \right. \\ &\quad \left. = c, \forall x \in S \right\}, \end{aligned} \quad (24)$$

and let $\mathcal{Q}_a = \cup_{\sigma \in M(S)} \mathcal{Q}_a(\sigma)$. Then, $q_a \in \mathcal{Q}_a(\pi)$ for the stationary distribution π of q . In other words, $\{X(t)\}$ is a reacting system if and only if $(q_a, \pi) \in \mathcal{Q}_a$. The question is what is $\mathcal{Q}_d$ for q with $\{q_a, q_d\}$ to be Γ -reversible in structure with respect to $\{\mathcal{Q}_a, \mathcal{Q}_d\}$. The answer is immediate from Lemma 2; namely, we must have

$$\mathcal{Q}_d(\sigma) = \{g_d \in \mathcal{T}(\sigma); \tilde{g}_a \in \mathcal{Q}_a(\sigma)\}, \quad \sigma \in M(S),$$

and therefore, recalling that $\tilde{g}_a(x, x') = \frac{\pi(x')}{\pi(x)} g_d(x', x)$ for $\pi(x) > 0$,

$$\begin{aligned} \mathcal{Q}_d(\sigma) &= \left\{ g_d \in \mathcal{T}(\sigma); \exists c > 0, \sum_{x' \in S} \sigma(x') g_d(x', x) \right. \\ &= c \sigma(x), \forall x \in S \left. \right\}, \sigma \in M(S). \end{aligned} \quad (25)$$

Thus, we put $\mathcal{Q}_d = \cup_{\sigma \in M(S)} \mathcal{Q}_d(\sigma)$.

Let q_a and q_d be a subtransition rate function of q , and assume that q has its stationary distribution π , then the condition for $q_d \in \mathcal{Q}_d(\pi)$ of Equation 25 can be written as, for some $\beta > 0$,

$$\sum_{x' \in S} \pi(x') q_d(x', x) = \beta \pi(x), \quad x \in S, \quad (26)$$

which is called *quasi-reversibility* in the literature (see, e.g., Ref. 4). Thus, we have the following theorem with help of Lemmas 2 and 4.

Theorem 1. $\{\mathcal{Q}_a, \mathcal{Q}_d\}$ defined through Equations 24 and 25 is Γ -reversible in structure. Let $\{X(t)\}$ be the Markov chain with transition rate functions (Eq. 23) for the reacting system with Poisson arrivals, and assume that this Markov chain has a stationary distribution π . Then, the following conditions are equivalent.

- (c1) $\{\tilde{X}(t)\}$ is also a reacting system.
- (c2) $\{X(t)\}$ with $\{q_a, q_b\}$ is Γ -reversible in structure with respect to $\{\mathcal{Q}_a(\pi), \mathcal{Q}_d(\pi)\}$.
- (c3) $\{X(t)\}$ is quasi-reversible, that is, Equation 26 holds for some $\beta > 0$.
- (c4) The departure process N_d from the reacting system is the Poisson process with rate β that is independent of the future evolution of the Markov chain $\{X(t)\}$.

Example 1. [M/M/1 batch service queue]. Modify the M/M/1 queue in such a way that a batch of customers depart at the service completion instant subject to the following rule. All customers depart if a requested batch size is greater than

the number of customers in the system at that moment. Otherwise, the requested number of customers depart. It is assumed that the batch sizes to be requested are independently and identically distributed with a finite mean. We call this model M/M/1 batch service queue. This queue does not have Poisson departures if all batch departures are counted as departures, but it does if we only count full batches, that is, the departing batches whose sizes meet those to be requested. Thus, this reacting system is reversible in structure if full batches are only counted as departures. Details on this model can be found in Sect. 2.6 of [4].

In Theorem 1, we have assumed Poisson arrivals. It may be questioned what will occur if the arrival process is not Poisson. To answer it, we consider an external source to produce arrivals as another reacting system that is independent of the original reacting system, where departures from the latter system become arrivals to the external source but do not cause any state changes of the source. Thus, we have the closed system in which the two reacting systems are cyclically connected. If the time-reversed model has the same structure, it is not hard to see that the external source produces Poisson arrivals and departures from the original system are also Poisson. Hence, the Poisson arrivals arise under the reversibility in structure of this cyclic model.

A reacting system with Poisson arrivals can model not only a single-node queue but also a network of queues if the state space S is appropriately chosen. A problem is whether the reversibility enables us to get the stationary distribution. Obviously, this is easier for a smaller system. This motivates us to consider reacting systems as nodes of a network of queues and to construct the stationary distribution of the network from those of reacting systems of Poisson arrivals. This program is executed in the section titled "Queueing Network and Product Form."

Another question on the reacting system is whether or not we can consider arrival processes depending on the state of the reacting system. We solve this problem incorporating

exogenous arrivals as one of departures suitably extending the state space S . This is done in the section titled “Self-Reacting System and Balanced Departure.”

Before looking at those problems, we will discuss a concrete example of quasi-reversibility.

SYMMETRIC SERVICE

The examples in the section titled “Queue and Reacting System” are reversible in structure, but have no internal state transitions. In this section, we introduce the reacting system that has internal state transitions. For this, we classify customers by types, and split the transition rate functions by them.

Let T be the set of customer types and let arrivals and departures be classified by customer types. We split p_a, q_d, α and β into p_{au}, q_{du}, α_u and β_u with $u \in T$, respectively. Thus, the transition rate function of the Markov chain is changed to

$$q(x, x') = \sum_{u \in T} (\alpha_u p_{au}(x, x') + q_{du}(x, x')) + q_1(x, x'), \quad x, x' \in S.$$

Assume that q has a stationary distribution π . Then, similar changes are made for the time-reversed model, and all the arguments are parallel for the reversibility. For example, the quasi-reversibility condition (Eq. 26) is changed to

$$\sum_{x' \in S} \pi(x') q_{du}(x', x) = \beta_u \pi(x), \quad x \in S, u \in T. \quad (27)$$

Let $U = \{au, du; u \in T\}$, and let Γ be the reflective permutation such that $\Gamma(au) = du$ for all $u \in T$. We define $Q_{au}(\pi)$ and $Q_{du}(\pi)$ similarly to $Q_a(\sigma)$ and $Q_d(\sigma)$ of Equations 24 and 25.

To describe the service discipline, we assume that there are infinitely many service positions numbered as $1, 2, \dots$, and customers in the system are allocated to positions 1 to n when n customers are in system. We further assume that each x in the

state space S has the following form when n customers are in system.

$$x = (n, \{(u_\ell, w_\ell); \ell = 1, 2, \dots, n\}), \\ u_\ell \in T, w_\ell \in \{1, 2, \dots\},$$

where u_ℓ and w_ℓ are the type and remaining service stage, respectively, of a customer in position ℓ . Let k_u be the service stage of a newly arriving customer of type u , and let η_{uj} be the completion rate of the stage j , that is, the sojourn time at the stage j is exponentially distributed with mean $1/\eta_{uj}$. We assume the following dynamics under the state x .

- (d1) A type u customer arrives and chooses position i among $\{1, 2, \dots, n+1\}$ with probability $\delta(i, n+1)$, and customers in positions $i, i+1, \dots, n$ move to $i+1, i+2, \dots, n+1$. That is, x is changed to x' :

$$x' = (n+1, \{(u_\ell, w_\ell); \ell = 1, 2, \dots, i\}, (u, k_u), \{(u_\ell, w_\ell); \ell = i+1, i+2, \dots, n\}).$$

- (d2) A type u_i customer in position i with $w_i = 1$ departs with rate $\gamma(i, n)\eta_{u_i 1}$, and customers in positions $i+1, i+2, \dots, n$ move to $i, i+1, \dots, n-1$. That is, x is changed to x' :

$$x' = (n-1, \{(u_\ell, w_\ell); \ell = 1, 2, \dots, i-1\}, \{(u_\ell, w_\ell); \ell = i+1, i+2, \dots, n\}).$$

- (d3) A type u_i customer in position i with $w_i \geq 2$ decreases its remaining service stage by 1 with rate $\gamma(i, n)\eta_{u_i w_i}$, and customers in positions $\ell \neq i$ are unchanged. That is, x is changed to x' :

$$x' = (n, \{(u_\ell, w_\ell); \ell = 1, 2, \dots, i-1\}, (u_i, w_i - 1), \{(u_\ell, w_\ell); \ell = i+1, i+2, \dots, n\}).$$

Note that (d1), (d2), and (d3) uniquely specify p_a, q_d , and q_1 . This reacting system is fairly general, but it is hard to get the stationary distribution even for Poisson

arrivals. Thus, we consider the simpler situation assuming that, for each $n \geq 1$,

$$\phi(n)\delta(\ell, n) = \gamma(\ell, n), \quad \ell = 1, 2, \dots, n, \quad (28)$$

where $\phi(n) = \sum_{\ell=1}^n \gamma(\ell, n)$. A service discipline satisfying this condition is referred to as *symmetric service* (see, e.g., Ref. 1). This service discipline includes processor sharing and preemptive last-come last-served, but cannot be first-come and first-served except for exponentially distributed service times.

It is well known that the reacting system with Poisson arrivals and symmetric service, which is called a *symmetric queue*, has the stationary distribution π :

$$\begin{aligned} \pi(n, \{(u_\ell, w_\ell); \ell = 1, 2, \dots, n\}) \\ = c^{-1} \prod_{\ell=1}^n \frac{\alpha_{u_\ell}}{\phi(\ell)\eta_{u_\ell w_\ell}}, \quad 1 \leq w_\ell \leq k_{u_\ell}, \end{aligned}$$

if it exists, where c is the normalizing constant (e.g., see Ref. 4). Furthermore, the quasi-reversibility (Eq. 27) holds, and therefore $\tilde{q}_{ud} \in \mathcal{Q}_{du}(\pi)$, where

$$\tilde{q}_{du}(x, x') = \frac{\pi(x')}{\pi(x)} \alpha p_{au}(x', x), \quad x, x' \in S.$$

Thus, the symmetric queue is Γ -reversible in structure with respect to $\{\mathcal{Q}_{au}(\pi), \mathcal{Q}_{du}(\pi); u \in T\}$. Furthermore, we can verify that

$$q_I(x, x') = \tilde{q}_I(x, x'), \quad x, x' \in S.$$

These facts are particularly useful in incorporating symmetric queues as nodes of a network.

In symmetric service, the service amount of type u customer is the sum of k_u independent exponentially distributed random variables with means $1/\eta_{uk_u}, 1/\eta_{u(k_u-1)}, \dots, 1/\eta_{u1}$. Hence, if we let $\eta_{uj} = k_u \zeta_u$, then the service amount distribution of a type u customer is a k_u -order Erlang distribution with mean ζ_u . Furthermore, if type u is split to finitely many subtypes and if each subtype has finitely many stages, then the amount of work for type u customer is subject to a mixture of Erlang distributions. Thus, we can approximate any service amount distribution by this finitely many stage model.

SELF-REACTING SYSTEM AND BALANCED DEPARTURE

We modify the reacting system so that it includes the exogenous source as a part of the system, and departures are immediately transferred to arrivals. We allow having different types for arrivals and departures. Let T be the set of types. In this section, an element of T may represent characteristics other than a type of customer. For example, it may represent batch sizes of arrivals and departures and their vectors. We slightly change the dynamics (b1) and (b2) while retaining (b3).

- (e1) An entity $u \in T$ is released under state x with rate $q_{du}(x, y)$ changing state x to y .
- (e2) A released entity $u \in T$ is transferred to entity u' under state y with probability $r(u, y, u')$, where

$$\sum_{u' \in T} r(u, y, u') = 1, \quad u \in T, y \in S.$$

- (e3) A transferred entity u' under state $y \in S$ changes the state from y to $x' \in S$ with probability $p_{au'}(y, x')$, where $\sum_{x' \in S} p_{au'}(y, x') = 1$ for each $u' \in T$ and $y \in S$.

We assume that (e2) and (e3) instantaneously follow after (e1). Then, we can define the transition rate function q of the Markov chain $\{X(t)\}$ as

$$\begin{aligned} q(x, x') = \sum_{u, u' \in T, y \in S} q_{(u, y, u')}^{(D \rightarrow A)}(x, x') \\ + q_i(x, x'), \quad x, x' \in S, \end{aligned} \quad (29)$$

where q_I is a transition rate function for internal transitions, and

$$q_{(u, y, u')}^{(D \rightarrow A)}(x, x') = q_{du}(x, y) r(u, y, u') p_{au'}(y, x'). \quad (30)$$

We refer to the model described by this Markov chain as a *self-reacting system*. One may think of r as a routing probability matrix. For each u, u', y , we denote the set of pairs (g, σ) of a transition rate function g of the

form (Eq. 30) for some q_{du} , r and $p_{qu'}$ and measure σ on S to support q by $\mathcal{Q}_{(u,y,u')}^{(\mathcal{D} \rightarrow \mathcal{A})}$.

By ν , we denote the solution of the following traffic equation for each $y \in S$,

$$\sum_{u' \in T} \nu(u', y) r(u', y, u) = \nu(u, y), u \in T, y \in S. \quad (31)$$

We always assume that the solution ν exists and $\nu(u, y) > 0$ if $r(u', y, u) > 0$. This existence is always the case if T is a finite because $\{r(u, y, u'); u, u' \in S\}$ is a transition probability matrix for each $y \in S$. However, ν may not be unique not only because any multiplication with a function of y is again a solution but also because the transition probability matrix may not be irreducible. Nevertheless, it will be uniquely determined under certain reversibility in structure (see Remark 3 below).

Let σ be a supporting measure for the transition rate function q , that is, $\sigma \in M_{\text{sup}}(q)$. Of course, the stationary distribution of q is such a measure, but we do not restrict σ to be so. Define

$$\begin{aligned} & \tilde{q}_{(u,y,u')}^{(\mathcal{D} \rightarrow \mathcal{A})}(x, x') \\ &= \begin{cases} \frac{\sigma(x')}{\sigma(x)} q_{(u',y,u)}^{(\mathcal{D} \rightarrow \mathcal{A})}(x', x), & \sigma(x) > 0, x, x' \in S, \\ 0, & \text{otherwise,} \end{cases} \end{aligned}$$

and

$$\begin{aligned} & \tilde{q}_I(x, x') \\ &= \begin{cases} \frac{\sigma(x')}{\sigma(x)} q_I(x', x), & \sigma(x) > 0, x, x' \in S, \\ 0, & \text{otherwise.} \end{cases} \end{aligned}$$

Let $U = \{(u, y, u'); u, u' \in T, y \in S\}$, and let Γ be the permutation such that $\Gamma((u, y, u')) = (u', y, u)$ for $u, u' \in T$ and $y \in S$. This Γ is clearly reflective. We would like to find under what conditions we have $(\tilde{q}_{(u',y,u)}^{(\mathcal{D} \rightarrow \mathcal{A})}, \sigma) \in \mathcal{Q}_{(u',y,u)}^{(\mathcal{D} \rightarrow \mathcal{A})}$ for all $(u, y, u') \in U$.

We first note that $(\tilde{q}_{(u',y,u)}^{(\mathcal{D} \rightarrow \mathcal{A})}, \sigma) \in \mathcal{Q}_{(u',y,u)}^{(\mathcal{D} \rightarrow \mathcal{A})}$ is equivalent to stating that there are some $\tilde{q}_{du'}$, $\tilde{r}$ and $\tilde{p}_{au}$ satisfying

$$\begin{aligned} & \sigma(x) q_{du}(x, y) r(u, y, u') p_{au'}(y, x') \\ &= \sigma(x') \tilde{q}_{du'}(x', y) \tilde{r}(u', y, u) \tilde{p}_{au}(y, x). \end{aligned} \quad (32)$$

Define β , $\tilde{\beta}$, $\tilde{r}$, $\tilde{p}_{au}$, and $\tilde{q}_{au}$ as

$$\begin{aligned} \beta(u, y) &= \sum_{x \in S} \sigma(x) q_{du}(x, y), \\ \tilde{\beta}(u', y) &= \sum_{u \in T} \beta(u, y) r(u, y, u'), \\ \tilde{r}(u', y, u) &= \frac{\beta(u, y)}{\tilde{\beta}(u', y)} r(u, y, u'), \\ \tilde{q}_i(x, x') &= \frac{\sigma(x')}{\sigma(x)} q_i(x', x), \\ \tilde{p}_{au}(y, x) &= \frac{\sigma(x)}{\beta(u, y)} q_{du}(x, y), \\ \tilde{q}_{au}(x', y) &= \frac{\beta(u', y)}{\sigma(x')} p_{au'}(y, x'). \end{aligned}$$

Then, we can verify (Eq. 32), that is, we always have $(\tilde{q}_{(u,y,u')}^{(\mathcal{D} \rightarrow \mathcal{A})}, \sigma) \in \mathcal{Q}_{(u,y,u')}^{(\mathcal{D} \rightarrow \mathcal{A})}$ for all $(u, y, u') \in U$. Thus, no condition is needed for q of the self-reacting system to be Γ -reversible in structure except for the existence of a supporting measure σ . This fact exactly explains the reversibility in (3) of the section titled "Introduction." The problem is that the reversibility in structure gives no clue to compute σ as the stationary distribution.

To get out this situation, we consider a stronger reversibility condition. For this, we assume that the routing function $\tilde{r}$ is identical to the time reversal of r with respect to its stationary measure ν of Equation 31; that is, we assume that

$$\tilde{r}(u', y, u) = \frac{\nu(u, y)}{\nu(u', y)} r(u, y, u'), u, u' \in T, y \in S. \quad (33)$$

This is equivalent to $\beta = \tilde{\beta} = \nu$, which is further equivalent to

$$\sum_{x' \in S} \sigma(x') q_{du}(x', x) = \nu(u, x), u \in T, x \in S. \quad (34)$$

We denote the subset of $\mathcal{Q}_{(u,y,u')}^{(\mathcal{D} \rightarrow \mathcal{A})}$ which satisfies (Eq. 34) for some ν of Equation 31 by $\mathcal{Q}_{(u,y,u')}^{(\mathcal{D} \rightleftharpoons \mathcal{A})}$. We refer to a self-reacting system with $q_{(u,y,u')}^{(\mathcal{D} \rightarrow \mathcal{A})} \in \mathcal{Q}_{(u,y,u')}^{(\mathcal{D} \rightleftharpoons \mathcal{A})}(\sigma)$ for all $(u, y, u') \in U$ and some $\sigma \in M_{\text{sup}}(q)$ as a self-reacting system with a reversible routing mechanism

because Equation 33 is equivalent to stating that $\tilde{r}$ has an invariant measure $\tilde{v}$ such that

$$v(u, y) = \tilde{v}(u, y), \quad u \in T, x \in S,$$

where $\mathcal{Q}_{(u, y, u')}^{(\mathcal{D} \rightarrow \mathcal{A})}(\sigma) = \{g \in \mathcal{T}(\sigma); (g, \sigma) \in \mathcal{Q}_{(u, y, u')}^{(\mathcal{D} \rightarrow \mathcal{A})}(\sigma)\}$.

Thus, we have the following theorem.

Theorem 2. $\{\mathcal{Q}_{(u, y, u')}^{(\mathcal{D} \rightarrow \mathcal{A})}; (u, y, u') \in T \times S \times S\}$ is always Γ -reversible in structure. If the Markov chain $\{X(t)\}$ with transition rate function q given by Equation 29 has a stationary distribution π and $q_{(u, y, u')}^{(\mathcal{D} \rightarrow \mathcal{A})} \in \mathcal{Q}_{(u, y, u')}^{(\mathcal{D} \rightarrow \mathcal{A})}(\pi)$, that is, it is a self-reacting system, then the time-reversed Markov chain $\{\tilde{X}(t)\}$ is also a self-reacting system, and the following conditions are equivalent.

- (f1) $\{X(t)\}$ is Γ -reversible in structure with respect to $\{\mathcal{Q}_{(u, y, u')}^{(\mathcal{D} \rightarrow \mathcal{A})}(\pi); (u, y, u') \in U\}$; that is, Equation (34) is satisfied for $\sigma = \pi$.
- (f2) $\{X(t)\}$ represents the self-reacting system with a reversible routing mechanism.
- (f3) $\{\tilde{X}(t)\}$ is a self-reacting system with a routing function $\tilde{r}$ of Equation 33.

Remark 3. v is uniquely determined by Equation (34) if the stationary distribution π is given.

We now construct the stationary distribution from the solution of the traffic equation 31. From the stationary equation 5, the stationary distribution π must satisfy

$$\pi(x) = \frac{1}{a(x)} \sum_{x' \in S} \pi(x') q(x', x),$$

where $a(x) = \sum_{x' \in S} q(x', x)$. Substituting q of Equation 29 into this equation and using the traffic equation 31 and Equation 34 with

$\sigma = \alpha\pi$ for some constant $\alpha > 0$, we have

$$\begin{aligned} \pi(x) &= \frac{1}{a(x)} \sum_{x' \in S} \pi(x') \left(\sum_{y \in S} \sum_{u, u' \in T} q_d(x', y, u') \right. \\ &\quad \left. r(u', y, u) p_a(u, y, x) + q_i(x', x) \right) \\ &= \frac{1}{a(x)} \left(\alpha \sum_{y \in S} \sum_{u, u' \in T} v(y, u') r(u', y, u) \right. \\ &\quad \left. p_a(u, y, x) + \sum_{x' \in S} \pi(x') q_i(x', x) \right) \\ &= \frac{1}{a(x)} \left(\alpha \sum_{y \in S} \sum_{u \in T} v(y, u) p_a(u, y, x) \right. \\ &\quad \left. + \sum_{x' \in S} \pi(x') q_i(x', x) \right). \end{aligned}$$

We assume

$$(e4) \quad \tilde{q}_I(x, x') = q_I(x, x') \text{ for } x', x \in S \text{ and } b(x) \equiv \sum_{x' \in S} q_I(x, x') < a(x) \text{ for all } x \in S.$$

Then π is uniquely determined by

$$\pi(x) = \frac{\alpha}{a(x) - b(x)} \sum_{y \in S} \sum_{u \in T} v(y, u) p_a(u, y, x), \quad x \in S. \quad (35)$$

Thus we can construct the stationary distribution π from v in this case.

Example 2. [Balanced departure under symmetric service]. Suppose that a self-reacting system satisfies the condition (e4). We consider conditions to have Equation (34) for this network. Define Φ as

$$\Phi(x) = \frac{1}{a(x) - b(x)} \sum_{y \in S} \sum_{u \in T} v(y, u) p_a(u, y, x), \quad x \in S. \quad (36)$$

We assume that state x is uniquely determined by y and u when entity u is released under state $x \in S$. Denote this x by $g(y, u)$, and q_d as

$$q_d(x, y, u) = \frac{v(y, u)}{\Phi(x)} \mathbf{1}(x = g(y, u)), \quad x, y \in S, u \in T. \quad (37)$$

We refer to this departure rate as Φ -balanced according to the terminology used in Ref. 6 (see also Example 4 below). Then, if $\sum_{x \in S} \Phi(x) < \infty$, we choose $\alpha = (\sum_{x \in S} \Phi(x))^{-1}$, and let

$$\pi(x) = \alpha \Phi(x), \quad x \in S. \quad (38)$$

It is easy to check that this π is indeed the stationary distribution and the reversibility condition (34) is satisfied. Thus, by Theorem 2, if q_d is given by Equation 37 and if (e4) is satisfied, then we have the stationary distribution π of Equation 38 for Φ of Equation 36. This self-reacting system has a reversible routing mechanism.

Example 3. [Batch movement network]. We further specialize the self-reacting system with a reversible routing mechanism of Example 2 assuming that there are no internal state transitions, that is, $b(x) \equiv 0$. Let $S = \mathbb{Z}_+^n$ and $T = \mathbb{Z}_+^{n+1}$, that is, its state is an n -dimensional vector with nonnegative integer entries. We assume that $q_d(x, y, u) > 0$ if and only if $y = x - u^+$, where $u^+ = (u_1, u_2, \dots, u_n)$ for $u = (u_0, u_1, \dots, u_n) \in T$. We further assume that $r(u, y, u') > 0$ if and only if $|u| = |u'|$, where $|u| = u_0 + u_1 + \dots + u_n$.

This system can be considered as an open queueing network with n nodes and batch movements, where the i th entry of $x \in S$ represents the number of customers at node i , and the j th entry of $u \in S$ is a departing batch for $j \neq 0$ while u_0 is a departing batch from an external source for $q_d(x, y, u) > 0$. Furthermore, the u are transferred to u' under each state y not changing their total numbers. It is notable that, if $u_0 = 0$ always holds, then T can be reduced to $\mathbb{Z}^n$, and the model is considered as a closed network. This model is referred to as a *queueing network with batch movements*.

We assume that $q_d(x, y, u) > 0$ only if $y = x - u^+$ and $p_a(u, y, x) > 0$ only if $x = y + u^+$. These assumptions are reasonable for batch movements. Then, $q_d(x, y, u) > 0$ if and only if

$p_a(u, y, x) > 0$ and Equation 37 becomes

$$q_d(x, y, u) = \frac{v(x - u^+, u)}{\Phi(x)} 1(y = x - u^+), \quad x, y \in S, u \in T. \quad (39)$$

We show that we can choose an arbitrary Φ . For this, we need to verify (Eq. 36). For the batch movement network, Equation 36 becomes

$$\Phi(x) = \frac{1}{a(x)} \sum_{u \in T} v(x - u^+, u) 1(x - u^+ \in S), \quad x \in S.$$

However, this automatically holds because

$$\begin{aligned} a(x) &= \sum_{x' \in S} \sum_{y \in S} \sum_{u, u' \in T} q_d(x, y, u) \\ &\quad \times r(u, y, u') p_a(u', y, x') \\ &= \frac{1}{\Phi(x)} \sum_{u \in T} v(x - u^+, u) \\ &\quad \times 1(x - u^+ \in S), \quad x \in S. \end{aligned}$$

Hence, we can choose an arbitrary Φ in Equation 39 as long as it is a positive-valued function. This model is called a *linear network* in Ref. 7. We refer to it as a *batch movement network with balanced departure*. There is significant literature on this class of networks (see, e.g., Refs 8–10).

If all batch sizes are units, then the batch movement network is reduced to the standard queueing network with single arrivals and departures.

Example 4. [State independent routing]. We consider a special case of the batch movement network with balanced departure of Example 3 in which $r(u, y, u')$ is independent of y . This model is said to have *independent routing*.

In this network, $v(y, u)$ can be independent of y , so it can be written as $\Psi(y)v(u)$ for an arbitrary positive-valued function Ψ on S and the solution v of the traffic equation 31 which

is a function on T . Thus, Equation 39 becomes

$$q_d(x, y, u) = \frac{\Psi(x - u^+)v(u)}{\Phi(x)} 1(y = x - u^+),$$

$$x, y \in S, u \in T, \quad (40)$$

where Ψ and Φ in Equation 39 can be arbitrary as long as they are positive-valued functions. Furthermore, if $v(u)$ is of the form $\prod_{i=1}^n w_i^{u_i}$ for positive constants $w_1, w_2, \dots, w_n$, then v is included in $\Psi(x - u^+)/\Phi(x)$ as

$$v(u) = \prod_{i=1}^n w_i^{u_i} = \frac{v(x)}{v(x - u^+)}.$$

Thus, Equation 40 is further simplified as

$$q_d(x, y, u) = \frac{\Psi(x - u^+)}{\Phi(x)} 1(y = x - u^+),$$

$$x, y \in S, u \in T, \quad (41)$$

and, if the stationary distribution exists, then it is given by

$$\pi(x) = C\Phi(x) \prod_{i=1}^n w_i^{x_i}, \quad x \in S,$$

where C is the normalizing constant. Otherwise, this π with $C = 1$ is a stationary measure. This model has been widely discussed in the literature. For example, Serfozo [6] called it the *Whittle network* with Φ -balanced departure intensities (see Theorem 1.48 of [6]). There are a lot of applications of this special case to telecommunication networks (e.g., see Ref. 11).

QUEUEING NETWORK AND PRODUCT FORM

We return to reacting systems. We use them here as nodes of a queueing network with Markovian routing, where the external source is included as one of those nodes. Consider a queueing network with n nodes, numbered as $1, 2, \dots, n$. We also have an external source as node 0. Let

$$J = \{0, 1, \dots, n\}.$$

Each node i is a reacting system with state space S_i , departure rate $q_d^{(i)}$, internal transition rate $q_I^{(i)}$, and arrival probability function $p_a^{(i)}$. Let T_i be the set of customer types arriving at and departing from node i . We assume the following dynamics.

- (g1) A departure of type $u_i \in T_i$ customer from node i occurs under state $x_i \in S_i$ with rate $q_{du_i}^{(i)}(x_i, x'_i)$ which changes the state x_i to $x'_i \in S_i$.
- (g2) A type u_i customer departing from node i goes to node j as type u_j customer with probability $r(iu_i, ju_j)$ independently of everything else. It is assumed that

$$\sum_{j \in J} \sum_{u_j \in T_j} r(iu_i, ju_j) = 1, \quad (i, u_i) \in J \times T_i.$$

- (g3) An arriving type u_j customer at node j under state $x_j \in S_j$ changes the state to $x'_j \in S_j$ with probability $p_{au_j}^{(j)}(x_j, x'_j)$. It is assumed that

$$\sum_{x'_j \in S_j} p_{au_j}^{(j)}(x_j, x'_j) = 1,$$

$$(u_j, x_j) \in T_j \times S_j, j \in J.$$

- (g4) The state $x_i \in S_i$ at node i changes to $x'_i \in S_i$ with rate $q_I^{(i)}(x_i, x'_i)$ not producing any departure.

We model this network by a continuous-time Markov chain $\{X(t)\}$. Its state space S is given by

$$S = S_0 \times S_1 \times \dots \times S_n$$

and its transition rate function q is given by

$$q(x, x') = \sum_{i, j \in J} \sum_{u \in T_i} \sum_{v \in T_j} q_{iu, jv}^{(d \rightarrow a)}(x, x') + \sum_{i \in J} q_I^{(i)}(x_i, x'_i),$$

where

$$q_{iu, jv}^{(d \rightarrow a)}(x, x') = \begin{cases} q_{du}^{(i)}(x_i, x'_i) r(iu, jv) p_{av}^{(j)}(x_j, x'_j) \\ \prod_{k \neq i, j} 1(x_k = x'_k), & i \neq j, \\ \sum_{y_i \in S_i} q_{du}^{(i)}(x_i, y_i) r(iu, iv) \\ p_{av}^{(j)}(y_j, x'_j) \prod_{k \neq i} 1(x_k = x'_k), & i = j. \end{cases} \quad (42)$$

We refer to the model described by this transition rate as a *network with reacting nodes and Markovian routing*.

We aim to construct a time-reversed process of this network model. For this, we consider the reacting system of node i with Poisson arrivals with rate $\alpha_u^{(i)}$. We assume

- (g5) There exist positive $\{\alpha_{u_i}^{(i)}\}$ and $\{\beta_{u_i}^{(i)}\}$ such that the Markov chain with transition rate q_i given by

$$\begin{aligned} q_i(x_i, x'_i) = & \sum_{u_i \in T_i} \left(\alpha_{u_i}^{(i)} p_{au_i}^{(i)}(x_i, x'_i) \right. \\ & \left. + q_{du_i}^{(i)}(x_i, x'_i) \right) + q_i^{(i)}(x_i, x'_i), \\ & x_i, x'_i \in S_i, i \in J, \end{aligned} \quad (43)$$

has the stationary distribution π_i for each $\{\alpha_{u_i}^{(i)}\}$, and

$$\begin{aligned} \sum_{x'_i \in S_i} \sum_{u_i \in T_i} \pi_i(x'_i) q_{du_i}^{(i)}(x'_i, x_i) &= \beta_{u_i}^{(i)} \pi_i(x_i), \\ x_i, x'_i \in S_i, i \in J, \end{aligned} \quad (44)$$

$$\begin{aligned} \alpha_{u_j}^{(j)} &= \sum_{i \in J} \sum_{u_i \in T_j} \beta_{u_i}^{(i)} r(iu_i, ju_j), \\ j \in J, u_j \in T_j. \end{aligned} \quad (45)$$

Then, similarly to the reacting system with Poisson arrivals in the section titled “Queue and Reacting System,” we define the time-reversed reacting system and routing function in the following way:

$$\begin{aligned} \tilde{p}_{au_i}^{(i)}(x_i, x'_i) &= \frac{1}{\beta_{u_i}^{(i)}} \frac{\pi_i(x'_i)}{\pi_i(x_i)} q_{du_i}^{(i)}(x'_i, x_i), \\ & x_i, x'_i \in S_i, u_i \in T_i, \\ \tilde{q}_{du_i}^{(i)}(x_i, x'_i) &= \frac{\pi_i(x'_i)}{\pi_i(x_i)} \alpha_{u_i}^{(i)} p_{au_i}^{(i)}(x'_i, x_i), \\ & x_i, x'_i \in S_i, u_i \in T_i, \\ \tilde{q}_i^{(i)}(x_i, x'_i) &= \frac{\pi_i(x'_i)}{\pi_i(x_i)} q_i^{(i)}(x'_i, x_i), \quad (x_i, x'_i) \in S_i, \\ \tilde{r}(iu_i, ju_j) &= \frac{\beta_{u_j}^{(j)}}{\alpha_{u_i}^{(i)}} r(ju_j, iu_i). \end{aligned}$$

Let $U_i = \{(a, u); u \in T_i\}, \{(d, u); u \in T_i\}$ for each $i \in J$, and let $U = \prod_{i \in J} U_i$. Define the permutation Γ_i on U_i such that $\Gamma_i(\{(a, u); u \in T_i\}) = \{(d, u); u \in T_i\}$ for each $i \in J$, and define the permutation on U such that $\Gamma(\{v_i; v_i \in U_i, i \in J\}) = \{\Gamma(v_i); v_i \in U_i, i \in J\}$. Clearly, Γ is reflective. Let $\mathcal{Q}_{au}^{(i)}(\pi_i)$ and $\mathcal{Q}_{su}^{(i)}(\pi_i)$ be similarly defined on $\mathcal{Q}_a(\pi)$ and $\mathcal{Q}_d(\pi)$, respectively, of a reacting system (Eqs 24 and 25).

The following facts can be proved using Lemma 1 (see Ref. 4 for its proof).

Theorem 3. *If the network with reacting nodes and Markovian routing satisfies (g5), that is, each node i has a stationary distribution π_i and is quasi-reversible in separation, that is, the Markov chain with transition rate function q_i is Γ_i -reversible in structure with respect to $\{\mathcal{Q}_{au}^{(i)}(\pi_i), \mathcal{Q}_{du}^{(i)}(\pi_i); u \in T_i\}$ for each i , then it has the stationary distribution π given by $\pi = \prod_{i=1}^n \pi_i$, that is,*

$$\pi(x) = \prod_{i=0}^n \pi_i(x_i), \quad x \equiv (x_0, x_1, \dots, x_n) \in S. \quad (46)$$

Furthermore, this Markov chain is Γ -reversible in structure with respect to $\{\mathcal{Q}_{(i,u),(j,v)}^{(D=A)}(\pi); u \in T_i, v \in T_j, i, j \in J\}$, where $\mathcal{Q}_{(i,u),(j,v)}^{(D=A)}(\pi)$ is defined as the set of transition rate functions of the form (Eq. 42) satisfying Equation 44.

Example 5. A Jackson network is well known to have the product form stationary distribution, provided it is stable. This network is a special case of the network of Theorem 3. To see this, let $S = \mathbb{Z}_+^{n+1}$ and let

$$\begin{aligned} p_a^{(i)}(x, x') &= \begin{cases} 1(x = x')i = 0, \\ 1(x'_i = x_i + 1 \geq, x'_j = x_j, i \neq j), \\ i \neq 0, \end{cases} \\ q_d^{(i)}(x, x') &= \begin{cases} \lambda i = 0, \\ \min(x_i, s_i) \mu_i 1(x'_i = x_i - 1 \geq 0, \\ x'_j = x_j, i \neq j), i \neq 0, \end{cases} \\ r(iu, ju) &= p_{ij}. \end{aligned}$$

Then, the reacting system with $p_a^{(i)}, q_d^{(i)}$ and Poisson arrivals is reversible in structure, and it is not hard to see that (g4) is satisfied with $\alpha_{u_i}^{(i)} = \beta_{u_i}^{(i)}$ for all i and u_i . If we replace the i th reacting system for $i \neq 0$ in the Jackson network by a reacting system with symmetric service, (g4) is also satisfied. This network is called a *Kelly network* [1]. Its special case limited to some symmetric service is called a *BCMP network* [12], where the workload for service to be requested is generally distributed, but any distribution can be approximated by the distribution with finitely many stages.

There are examples for Theorem 3 in the other direction. A customer is said to be negative if it removes one customer without any other change at its arriving node; this was introduced by Gelenbe [13]. Such a customer is said to be a negative signal if it instantaneously moves around in a network according to a given Markovian routing until it meets an empty node or leaves the network. It is known that Theorem 3 can be applied to the *Jackson network with negative signals*. In this case, we may have $\alpha_{u_i}^{(i)} \neq \beta_{u_i}^{(i)}$ for some i and u_i . See Ref. 4 for a full description of those networks.

OTHER STOCHASTIC PROCESSES

We have mainly considered a continuous-time Markov chain. Reversibility in structure also may be considered for other stochastic processes. A discrete-time Markov chain is one of them. There is much literature for local balance, but those results are mostly parallel to those of the continuous-time case. They also can be reformulated by reversibility in structure.

Both Markov chains have discrete state spaces. To directly consider service times, we need continuous-valued components in the state of the system. A good model for this is a generalized semi-Markov process (GSMP) and its variants such as reallocatable GSMP (see, e.g., Refs 14 and 15). Roughly speaking, the states of those processes are the pairs of discrete state and positive real numbers, called *remaining lifetimes* (or *attaining*

lifetimes). If one of the remaining lifetimes expires, then it causes the transition of the discrete state, which may produce new lifetimes.

The GSMPs are particularly useful in proving the so-called insensitivity, which means that the stationary distribution depends on the lifetime distributions only through their means. This insensitivity holds if and only if certain partial balance holds, which is a spatial case of reversibility in structure. Under this condition, we again have the symmetric queues and their networks. There are some related results here if there are service interruptions that force customers to leave (see, e.g., Ref. 14). However, no new development has been made since the nineties.

There are some other stochastic processes related to queueing networks. For example, they are often considered using reflecting random walk or semi-Martingale reflecting Brownian motion (SRBM). Both are multidimensional and take values in the nonnegative orthant. Furthermore, the time-reversed process has been studied for general Markov processes (see, e.g., Ref. 16). It is known that SRBM on a polyhedral domain, which includes the nonnegative orthant as a special case, has the product form stationary distribution if and only if the so-called skew symmetric condition holds, which implies that the time-reversed process is also SRBM (see Theorem 1.2 of [17]).

CONCLUDING REMARKS

As we have seen, available models for queues and their networks are limited under reversibility in structure. Those models are still actively applied, but theoretical study is less active now. What can we do to gain more applicability? There are some comments here.

1. The reversibility described in this article has two ingredients. One is how strongly we set it up. In this article, we mainly considered this aspect for queueing network processes. Another is which class of stochastic processes

we take into consideration. We briefly discussed this issue in the section titled “Other Stochastic Processes.” If we take an appropriate class, say, not too small but not too large, then we may find more tractable models for queueing networks. This direction of study seems to be not well developed.

2. The existing studies for reversibility in queues have been intended to get the stationary distribution in closed form. This target may be too big, and it may be better to have smaller target. For example, tail asymptotic of the stationary distribution is one of them (see, e.g., Ref. 18). This may include reconsideration of the definition of reversibility in structure.

ACKNOWLEDGMENTS

The author is grateful to an anonymous referee for their thoughtful comments. The definition of reversibility in structure was greatly changed from its original form due to them.

REVIEWS OF MAINTENANCE LITERATURE AND MODELS

FRANCIS K. N. LEUNG
Department of Management
Sciences, City University of Hong
Kong, Hong Kong

INTRODUCTION

Modeling of the maintenance (i.e., inspection, overhaul, repair, replacement, etc.) of deteriorating systems has been of significant importance for the past 70 years, especially because of its applications in industry and medicine. There is an extensive literature on various types of preventive maintenance (PM) policies for stochastically failing single-unit and multiunit systems. In this article, we review part of the literature that deals with the problem of PM of a stochastically failing single-unit system. Notice that a unit has several or many components but is regarded as a single entity in either case, and is, respectively, called a *simple item* (e.g., a ball bearing) or a *complex system* (e.g., a car) subsequently. We emphasize how certain features of the various models affect their analysis and the conclusions that can be drawn from them. It should be noted that what we present in this article is only a very small portion of the maintenance field; so many mathematically outstanding papers have been omitted because of space considerations. However, many good review articles exist that provide an extensive overview of the field and can be helpful as guidance through the literature. We mention surveys by McCall [1], Pierskalla and Voelker [2], Sherif and Smith [3], Valdez-Flores and Feldman [4], and Wang [5] that detail much of the literature on single-unit deteriorating systems up to 2002; while surveys by Thomas [6], Cho and Parlar [7], and Dekker *et al.* [8] concentrate on multiunit deteriorating systems. These combined sets of papers list over

2000 references altogether. We also mention monographs written by Barlow and Proschan [9], Jardine [10], Nakagawa [11], and Wang and Pham [12], and handbooks edited by Ben-Daya *et al.* [13], Osaki [14], Pham [15], and Kobbacy and Murthy [16].

In the past, maintenance problems received little attention and research in this area did not have much impact. This is changing because of the increasing importance of the role of maintenance in the new industrial environment. Maintenance, if optimized, can be used as a key factor in an organization's efficiency and effectiveness. It also enhances the organization's ability to be competitive and meets its stated objectives.

Research in the area of maintenance management and engineering is on the rise. Over the past few decades, there has been tremendous interest and a great deal of research in the area of maintenance modeling and optimization. Models have been developed that cover a wide variety of maintenance problems. Although the subject of maintenance modeling is a late developer compared to other areas like production systems, the interest in this area is growing at an unprecedented rate.

MAINTENANCE POLICIES

This section provides a brief overview of the maintenance modeling research areas. It is not meant to be a complete review of maintenance models but rather act as an informative introduction to important maintenance modeling areas. Areas covered include replacement, repair and replacement, imperfect PM, condition-based maintenance (CBM), and inspection.

Maintenance strategies can be classified into three categories:

1. Corrective maintenance (CM), where replacement or repair is performed only at the time of failure. This may be

the appropriate strategy in some cases, such as when the hazard (also called *failure rate*) is constant and/or when the failure has no serious cost or safety consequences, or it is low on the priority list.

2. PM, where maintenance is performed on a scheduled basis with scheduled intervals often based on manufacturers' recommendations and experience with the equipment. This may involve replacement, repair, or both.
3. CBM, where maintenance decisions are based on the current condition of the equipment; thus avoiding unnecessary maintenance and performing maintenance activities only when they are needed to avoid failure. CBM relies on condition-monitoring techniques such as oil analysis, vibration analysis, and other diagnostic techniques to make maintenance decisions.

Implementing these strategies involves familiar maintenance activities like inspection, replacement, and repairs. In this section, we discuss representative models and modeling techniques dealing with maintenance strategies, including replacement, repair and replacement, imperfect PM, CBM, and inspection decisions. Replacement models are discussed first. They are of particular interest since they were among the earliest models developed. They were extended to include repairs and later to incorporate condition-monitoring information.

Replacement Models

In this section, we develop several basic replacement models. There are two kinds of replacement: failure replacement (a type of CM) and scheduled replacement (a type of PM). We are concerned with the latter whereby availability is increased and/or expected cost is reduced. Throughout this section, we assume that the lifetime of a simple item is governed by the known continuous-time distribution $F(x)$ for $x \geq 0$ with a finite mean μ , and further assume that there is an infinite number of new identical items available for replacement.

We are interested in minimizing the long-run expected cost rate (i.e., the expected cost per unit time in the steady state) or maximizing the limiting availability.

Age Replacement Models. Consider a renewal process with interarrival time distribution $F(x)$, which corresponds to the process of the item with only failure replacement. We define two scheduled replacement policies.

Definition 1. Age replacement: a simple item is replaced upon failure or at age T_a , whichever comes first.

Definition 2. Block replacement: a simple item or a complex system is replaced upon failure and at times $T_b, 2T_b, 3T_b, \dots$

First we discuss age replacement models, and then we develop block replacement models. Under an age replacement policy, an item is replaced upon failure or at age T_a , whichever comes first. Such a renewal process becomes a truncated renewal process with interarrival times $\{\min(X_n, T_a), n = 1, 2, \dots\}$. The stochastic behavior of such a process can be analyzed using the results of the renewal process [17].

We are only interested in the long-run expected cost rate. Let c_1 and c_2 denote the costs of a failure and a scheduled replacement, respectively. It is natural to assume that $c_1 > c_2$.

The long-run expected cost rate can be given by the expected cost per cycle divided by the expected duration per cycle, where a cycle terminates whenever a renewal (an item is replaced upon failure or at age T_a , whichever comes first) takes place. The long-run expected cost rate, using the renewal reward theorem (see, e.g., Theorem 3.6.1 of Ross [17]), is given by

$$C(T_a) = \frac{c_1 \Pr(X_n \leq T_a) + c_2 \Pr(X_n > T_a)}{E[\min(X_n, T_a)]}.$$

A cycle terminates at $\{\min(X_n, T_a), n = 1, 2, \dots\}$ and repeats itself again and again. Note that

$$\begin{aligned} E[\min(X_n, T_a)] &= \int_0^{T_a} x dF(x) + T_a \bar{F}(T_a) \\ &= \int_0^{T_a} \bar{F}(x) dx, \end{aligned}$$

where $\bar{F}(x) \equiv 1 - F(x) = \Pr(X_n > x)$; so we have

$$C(T_a) = \frac{c_1 F(T_a) + c_2 \bar{F}(T_a)}{\int_0^{T_a} \bar{F}(x) dx}. \quad (1)$$

Assume that there exists the density $f(x)$ of $F(x)$. Differentiating $C(T_a)$ with respect to T_a and equating the derivative to zero, we have

$$h(T_a) \int_0^{T_a} \bar{F}(x) dx - F(T_a) = \frac{c_2}{c_1 - c_2}, \quad (2)$$

where $h(x) = \frac{f(x)}{\bar{F}(x)}$, the hazard (or failure rate) function. Equation (2) is a nonlinear equation with respect to $T_a \geq 0$. Differentiating the left-hand side of Equation (2), we have

$$h'(T_a) \int_0^{T_a} \bar{F}(x) dx,$$

which is nonnegative (i.e., the left-hand side of Equation (2) is a monotonically increasing function) if we assume $\frac{dh(T_a)}{dT_a} \equiv h'(T_a) \geq 0$ (i.e., $F(T_a)$ is in the class of increasing failure rate (IFR) distributions). Because the left-hand side of Equation (2) equals zero at $T_a = 0$ and approaches $h(\infty)\mu - 1$ as $T_a \rightarrow \infty$ if $F(T_a)$ is IFR, we have the following theorem (Fig. 1).

Theorem 1.

- (i) If $h(x)$ is monotonically increasing and $h(\infty) > \frac{c_1}{\mu(c_1 - c_2)}$, then there exists a finite and unique T_a^* which satisfies Equation (2) and the resulting minimum cost rate is

$$C(T_a^*) = (c_1 - c_2)h(T_a^*). \quad (3)$$

- (ii) If $h(x)$ is monotonically increasing and $h(\infty) \leq \frac{c_1}{\mu(c_1 - c_2)}$, or $h(x)$ is nonincreasing, then the optimal policy is $T_a^* = \infty$, that is, there is no scheduled replacement and $C(\infty) = \frac{c_1}{\mu}$.

The proof of Theorem 1 is given in Osaki and Nakagawa [18].

Figure 1. Behavior of $C(T_a)$ and left-hand side (lhs) of Equation (2) for the IFR distribution.

Example 1.

Case (a):

The lifetime follows a 2-Erlang distribution with parameter λ (which is a special case of the gamma distribution with scale parameter $\alpha = \frac{1}{\lambda}$ and shape parameter $\beta = 2$), that is, $F(x) = 1 - (1 + \lambda x) e^{-\lambda x}$, where $\mu = \alpha\beta = \frac{2}{\lambda}$ is the mean lifetime. The hazard function is $h(x) = \frac{\lambda^2 x}{\lambda x + 1}$ and $h(\infty) = \lambda$.

If $h(\infty) = \lambda > \frac{\lambda c_1}{2(c_1 - c_2)}$, that is, $c_1 > 2c_2$, then there exists a finite and unique T_a^* satisfying Equation (2) and $C(T_a^*) = \frac{\lambda^2 T_a^* (c_1 - c_2)}{\lambda T_a^* + 1}$. If $c_1 \leq 2c_2$, the optimal policy is $T_a^* = \infty$, that is, there is no scheduled replacement and $C(\infty) = \frac{\lambda c_1}{2}$.

Case (b):

Consider the Weibull distribution $F(x) = 1 - e^{-\lambda x^\beta}$ with $\lambda > 0$ and $\beta > 1$. The corresponding hazard function is $h(x) = \lambda \beta x^{\beta-1}$ and the

Figure 2. Interpretations of the behavior for Models I, II, and III.

optimal replacement age is the unique solution to

$$h(T_a) \int_0^{T_a} e^{-\lambda x^\beta} dx - 1 + e^{-\lambda T_a^\beta} = \frac{c_2}{c_1 - c_2}.$$

The resulting minimum cost rate is $C(T_a^*) = (c_1 - c_2)h(T_a^*)$.

Block Replacement Models. For age replacement models, we have to observe the age of an item, which is sometimes difficult administratively. However, for block replacement models, we do not need to observe the age of an item, but replace at $T_b, 2T_b, 3T_b, \dots$, which is easier to administer in general (Definition 2). Here, we develop the following three variations of block replacement models (see Fig. 2, which is adapted from Osaki [19, p. 203]).

Model I: a failed item is replaced instantaneously at failure.

Model II: a failed item remains inoperable until the next scheduled replacement.

Model III (often called *minimal repair model*): a failed system undergoes minimal repair.

In general, Model I represents a typical block replacement model and is well known. Model II is a simple variation of Model I. Model III represents periodic replacement with minimal repair upon failure, where we assume that after each failure only minimal repair is performed so that the rate of occurrence of failure (ROCOF), denoted by $r(t)$, and the effective age of a system are not disturbed.

Minimal repair means that a failed system will function, after repair, with the same ROCOF and the same effective age as at the time of the last failure. For a minimal repair model where repair time is assumed to be negligible, a nonhomogeneous Poisson process (NHPP) in which the ROCOF is monotonic can provide at least a good first-order model for a deteriorating system [20]. In other words, failures constitute an NHPP with a suitable parametric form for ROCOF. Such a model can be justified since a system (e.g., a car) has many components that can fail so that replacing some failed components has very little effect on future system reliability.

Balaban and Singpurwalla [21, pp. 66–67] provided examples of minimal repair actions:

1. A TV set has stopped functioning because of the failure of an integrated circuit panel. The set functions as soon as the failed panel is replaced. If the other components are left alone, then the set is not like a new one and a minimal repair action has been performed.
2. A tire that has run several miles is punctured by a nail and goes flat; so the car using the tire is considered to have failed. A repair of the puncture restores the car to an operational status. If we assume that the puncture patch has not strengthened the tire by a significant amount, then a minimal repair action has been performed on the car.
3. A coronary occlusion may cause heart failure. Cardio pulmonary resuscitation (CPR) may revive the patient. Assuming revival without damage to vital organs, we may view CPR as a minimal repair action.

Model I. A failed item is replaced by a new identical one during the replacement interval T_b and the scheduled replacement for the nonfailed item is performed at $T_b, 2T_b, 3T_b, \dots$. Then the long-run expected cost rate is

$$C_1(T_b) = \frac{c_1 M(T_b) + c_2}{T_b} = \frac{c_1 \int_0^{T_b} m(t) dt + c_2}{T_b}, \quad (4)$$

where $M(t) = \sum_{n=1}^{\infty} F^{(n)}(t)$ is the renewal function with the underlying distribution $F(x)$, $F^{(n)}(t)$ is the n -fold convolution of $F(x)$ with itself, $m(t) = \frac{dM(t)}{dt}$ is the renewal density, c_1 is the cost of replacement for the failed item, and c_2 is the cost of scheduled replacement for the nonfailed item. To minimize the long-run expected cost rate in Equation (4), we obtain the following equation by differentiating $C_1(T_b)$ and equating the derivative to zero:

$$T_b m(T_b) - \int_0^{T_b} m(t) dt = \frac{c_2}{c_1}. \quad (5)$$

This is a necessary condition for the existence of a finite T_b^* and the resulting minimum cost

rate is

$$C_1(T_b^*) = c_1 m(T_b^*). \quad (6)$$

In general, by specifying the underlying distribution $F(x)$ we can obtain the renewal function $M(t)$ and renewal density $m(t)$, by which we can solve the nonlinear Equation (5).

Example 2. The lifetime follows a 2-Erlang distribution with parameter λ , that is, $F(x) = 1 - (1 + \lambda x)e^{-\lambda x}$.

The Laplace–Stieltjes (L–S) transform of $M(t)$ is

$$\tilde{M}(s) = \frac{\tilde{F}(s)}{1 - \tilde{F}(s)},$$

where $\tilde{F}(s) = \int_0^{\infty} e^{-sx} dF(x)$ is the L–S transform of $F(x)$.

The L–S transform of $F(x) = 1 - (1 + \lambda x)e^{-\lambda x}$ is

$$\tilde{F}(s) = \left(\frac{\lambda}{s + \lambda} \right)^2.$$

Therefore,

$$\begin{aligned} \tilde{M}(s) &= \frac{\left(\frac{\lambda}{s + \lambda} \right)^2}{1 - \left(\frac{\lambda}{s + \lambda} \right)^2} = \frac{\lambda^2}{s(s + 2\lambda)} \\ &= \frac{\lambda}{2s} - \frac{1}{4} \left(\frac{2\lambda}{s + 2\lambda} \right). \end{aligned}$$

Inversion obtains

$$M(t) = \frac{\lambda t}{2} - \frac{1 - e^{-2\lambda t}}{4},$$

and differentiation yields

$$m(t) = \frac{\lambda}{2} - \frac{\lambda e^{-2\lambda t}}{2}.$$

Equation (5) becomes

$$-\frac{\lambda T_b e^{-2\lambda T_b}}{2} + \frac{1 - e^{-2\lambda T_b}}{4} = \frac{c_2}{c_1}$$

or

$$e^{-2\lambda T_b} + 2\lambda T_b e^{-2\lambda T_b} = \frac{c_1 - 4c_2}{c_1}.$$

Since the left-hand side of the above equation is always positive, a finite solution exists

provided $c_1 > 4c_2$, that is, a failure replacement is at least four times more expensive than a scheduled replacement. We can draw the following conclusion: if $\frac{c_2}{c_1} \geq \frac{1}{4}$, we should perform only failure replacement. If $\frac{c_2}{c_1} < \frac{1}{4}$, there exists a finite and unique T_b^* that minimizes Equation (4) and the resulting minimum cost rate is $C_1(T_b^*) = \frac{\lambda c_1}{2}(1 - e^{-2\lambda T_b^*})$.

Model II. In the first model, we assumed that a failed item is detected instantaneously just after failure. In Model II, we assume that failure is detected only at $T_b, 2T_b, 3T_b, \dots$. An item is always replaced at $T_b, 2T_b, 3T_b, \dots$, but is not replaced at the time of failure and the item remains inoperable for the duration of time from the occurrence of failure until its detection. The expected duration from the occurrence of failure until its detection per cycle is given by

$$\int_0^{T_b} (T_b - x) dF(x) = \int_0^{T_b} F(x) dx.$$

The long-run expected cost rate is

$$C_2(T_b) = \frac{c_1 \int_0^{T_b} F(x) dx + c_2}{T_b}, \quad (7)$$

where c_1 is the cost of failure per unit time, and c_2 is the cost of scheduled replacement for the failed or nonfailed item. Comparing Equation (7) with Equation (4), we find a similar long-run expected cost rate, outside of the integrand.

Referring to Equation (5), we have

$$\begin{aligned} T_b F(T_b) - \int_0^{T_b} F(x) dx &= \int_0^{T_b} [F(T_b) - F(x)] dx \\ &= \frac{c_2}{c_1}. \end{aligned} \quad (8)$$

Assuming $T_b \rightarrow \infty$, we have

$$\lim_{T_b \rightarrow \infty} \int_0^{T_b} [F(T_b) - F(x)] dx = \int_0^{\infty} \bar{F}(x) dx = \mu.$$

It is easy to show that if $\mu > \frac{c_2}{c_1}$, there exists an optimal T_b^* which is a finite and unique solution to Equation (8).

Example 3. The lifetime follows a 2-Erlang distribution with parameter λ , that is, $F(x) =$

$1 - (1 + \lambda x) e^{-\lambda x}$, where $\mu = \frac{2}{\lambda}$ is the mean lifetime.

If $\lambda \geq \frac{2c_1}{c_2}$, we should not perform any scheduled replacement. If $\lambda < \frac{2c_1}{c_2}$, there exists a unique T_b^* satisfying

$$\frac{2 - e^{-\lambda T_b}(2 + 2\lambda T_b + \lambda^2 T_b^2)}{\lambda} = \frac{c_2}{c_1},$$

and the resulting minimum cost rate is

$$C_2(T_b^*) = c_1[1 - (1 + \lambda T_b^*)e^{-\lambda T_b^*}].$$

Model III (i.e., Minimal Repair Model). We assume that minimal repair is performed when a system fails, and the ROCOF, $r(t)$, and the effective age are not disturbed by each repair. If we consider a stochastic process $\{N(t), t \geq 0\}$ in which $N(t)$ represents the number of minimal repair actions up to time t , the process $\{N(t), t \geq 0\}$ is governed by an NHPP with mean value function

$$R(t) = \int_0^t r(s) ds.$$

Noting this fact, we have the following long-run expected cost rate for Model III:

$$C_3(T_b) = \frac{c_1 \int_0^{T_b} r(t) dt + c_2}{T_b}, \quad (9)$$

where c_1 and c_2 are the costs of minimal repair for the failed components and of replacement for the system, respectively. Comparing Equation (9) with Equation (4), we also have the same long-run expected cost rate except for the integrand.

Example 4. If we assume that the ROCOF has the same analytic form as the hazard function given in Example 1, we have the following two cases:

Case (a):

$$r(t) = \frac{\lambda^2 t}{\lambda t + 1}.$$

There exists a unique T_b^* satisfying

$$\frac{(\lambda T_b)^2}{\lambda T_b + 1} - \int_0^{T_b} \frac{\lambda^2 t}{\lambda t + 1} dt = \frac{c_2}{c_1},$$

or

$$\frac{(\lambda T_b)^2}{\lambda T_b + 1} - \lambda \int_0^{T_b} \left(1 - \frac{1}{\lambda t + 1}\right) dt = \frac{c_2}{c_1},$$

or

$$\ln(\lambda T_b + 1) - \frac{\lambda T_b}{\lambda T_b + 1} = \frac{c_2}{c_1},$$

and the resulting minimum cost rate is

$$C_2(T_b^*) = \frac{c_1 \lambda^2 T_b^*}{\lambda T_b^* + 1}.$$

Case (b):

Consider the power law process (PLP), denoted by $r(t) = \lambda \beta t^{\beta-1}$ for $t \geq 0$ with $\lambda > 0$ and $\beta > 1$. The optimal replacement interval is the unique solution to

$$(\beta - 1)\lambda T_b^\beta = \frac{c_2}{c_1},$$

or

$$T_b^* = \left[\frac{c_2}{c_1 \lambda (\beta - 1)} \right]^{\frac{1}{\beta}}.$$

The resulting minimum cost rate is $C(T_b^*) = c_1 r(T_b^*)$.

The popularity of the PLP is twofold: first, it can model deteriorating or improving systems; second, point estimators for the parameters have simple closed-form expressions and tests of hypotheses can be undertaken using existing tables. The PLP denoted and given by $r(t) = \lambda \beta t^{\beta-1}$ for $t \geq 0$ and $\lambda, \beta > 0$ is the most important ROCOF parametric form in an NHPP model. If $\beta > 1$, the ROCOF increases with time, as often happens with aging machinery. This is one of the two main conditions for determining if it is worth carrying out a scheduled replacement (the other condition is that the cost c_2 of a system replacement is much greater than the cost c_1 of a minimal repair action). But if $0 < \beta < 1$, the ROCOF decreases with time; hence, the PLP can model reliability growth as well. The homogeneous Poisson process (HPP), which has constant ROCOF, is a special case of the PLP with $\beta = 1$. Rigdon and Basu [22] gave a detailed discussion on the PLP.

There are three notes on using the PLP, or any other model, for event times, namely:

1. The PLP, often misleadingly called the *Weibull process* (this name is a misnomer since only the time to first failure has a Weibull distribution), is a useful and simple model for describing the failure times of a repairable complex system. The term PLP, a phrase describing the functional form of the ROCOF function, was introduced by Ascher and Feingold [20].
2. Note that the ROCOF, which is sometimes called the *failure rate*, should not be confused with the hazard, which is also sometimes known as the *failure rate*; see Ascher and Feingold [20, Chapter 8] for a discussion of poor terminology.
3. Rigdon and Basu [22, p. 259] have reached the conclusion that “using the PLP or any other model for event times, one clearly indicates the time that data collection started and the time that it ceased. This is necessary so that the appropriate analysis, that is, an analysis based on failure-truncated or time-truncated data, can be applied and maximum information can be obtained from the data. For time-truncated data, the time between the last failure and the termination of the test contains some information that should not be wasted.”

In addition, we add two notes on the absence of sufficient data relating to the maintenance problem that are of interest when finding plausible models to be fitted and validated:

1. To overcome the problem of data shortage, we can make use of the judgment of the engineers for the elicitation of a statistical point process. Methods for eliciting expert opinions, incorporating one's judgment about the quality of the expert opinions, and combining the opinions of several experts are given by Lindley [23] and Van Noortwijk *et al.* [24]. Kypris and Singpurwalla [25], and Guida *et al.* [26] individually considered the PLP, $r(t) = \lambda \beta t^{\beta-1}$, with λ and β being unspecified and subject

to Bayesian revision. A Bayesian approach with meaningfully chosen priors would bring improvement to the analysis because of its ability to incorporate expert knowledge and engineering information into the inferential mechanism [27]; however, the approach requires much more burdensome computation.

2. Baker and Scarf [28, p. 9] have indicated that “although large sample sizes are required to estimate the optimal value of a decision variable, such as the optimal inspection interval or replacement period, to a high accuracy, it has been shown that the cost (or downtime) which is optimized can be reduced to near its true minimum value even for small sample sizes, because of the quadratic nature of a minimum. In fact, the expected excess cost over the minimum cost is inversely proportional to the sample size. This means that even modest sample sizes would be sufficient for the practical use of sensible models for determining cost- (or downtime-) based maintenance policies.”

Holland and McLean [29], Aven [30], Kumar and Klefsjo [31], and Leung and Cheng [32] provided case studies which show that minimal repair models are a good means of achieving both effective and efficient maintenance.

The seminal ideas of age replacement and minimal repair models were first introduced in the classic paper by Barlow and Hunter [33]. Twenty years later, Nguyen and Murthy [34] extended both models to a hazard and a ROCOF that are reduced by each repair, but their subsequent growths are increasing functions of the number of previous repairs. Other extensions and variations of age replacement and block replacement are discussed in Dohi *et al.* [35].

Repair-Replacement Models using Geometric Processes

The work in this section is substantially based on Lam [36].

Definition 3. Given a sequence of random variables $G_1, G_2, \dots$. If for some $r > 0$, $\{G_n r^{(n-1)}, n = 1, 2, \dots\}$ forms a renewal process (RP), then $\{G_n, n = 1, 2, \dots\}$ is a geometric process (GP). The parameter r is called the *common ratio of the GP*.

Three specializations of a GP are given below:

If $r > 1$, then the GP is called a *decreasing GP*.

If $0 < r < 1$, then the GP is called an *increasing GP*.

If $r = 1$, then the GP reduces to an RP.

Therefore, for a deteriorating system, it is reasonable to assume that the successive operating times of the system form a decreasing GP, whereas the corresponding consecutive repair times constitute an increasing GP (Fig. 3). However, the replacement times for the system are usually stochastically the same, no matter how old the used system is; hence, they will form an RP. This is the motivation behind the introduction of the GP approach.

Two Types of GP Models. Before deriving the repair-replacement models, the following assumptions are stated:

1. At the beginning, a new system is used.
2. Whenever the system fails, it can be repaired. Let X_n be the survival time after the $(n - 1)$ th repair, then a sequence $\{X_n, n = 1, 2, \dots\}$ forms a decreasing GP with parameter $r_a > 1$, and $E(X_1) \equiv \mu_{X_1} > 0$.
3. Let Y_n be the repair time after the n th failure, then a sequence $\{Y_n, n = 1, 2, \dots\}$ forms an increasing GP with parameter $0 < r_b < 1$, and $E(Y_1) \equiv \mu_{Y_1} \geq 0$. Note that $\mu_{Y_1} = 0$ means that the repair time is negligible.
4. A sequence $\{X_n, n = 1, 2, \dots\}$ and a sequence $\{Y_n, n = 1, 2, \dots\}$ are independent.

Figure 3. A realization of the system.

5. An average operating cost rate is c_o , an average repair cost rate is c_f , and an average revenue rate of a working system is w .
6. The system may sometime be replaced by a new and identical one. An average replacement cost rate under policy T or N is c_{RT} or c_{RN} , respectively, and an average replacement downtime under policy T or N is u_{RT} or u_{RN} , respectively. Two kinds of replacement policies are considered in this model.
 - a. A replacement policy T is a policy in which we replace the system whenever the working age of the system reaches T , a continuous decision variable. The working age T of a system at time t is the cumulative survival time by time t , that is,

$$T = \begin{cases} t - V_n & \text{for } U_n + V_n \leq t \\ & < U_{n+1} + V_n, \\ U_{n+1} & \text{for } U_{n+1} + V_n \leq t \\ & < U_{n+1} + V_{n+1}, \end{cases} \quad (10)$$

where $U_n = \sum_{i=1}^n X_i$, $V_n = \sum_{i=1}^n Y_i$, and $U_0 = 0$, $V_0 = 0$.

- b. A replacement policy N is a policy in which we replace the system at the time of N th failure since the last replacement, a discrete decision variable.

Under replacement policy T or N , the problem is to determine an optimal replacement policy T^* or N^* , respectively, such that the long-run expected loss per unit total time or per unit operation time is minimized.

Let T_n be the time between the $(n-1)$ th replacement and the n th replacement with $T_0 = 0$, then $\{T_n, n = 1, 2, \dots\}$ forms an RP. Applying the renewal reward theorem, the long-run expected loss per unit time is

obtained by

$$l(T) \text{ or } l(N) = \frac{E(\text{loss incurred in a cycle})}{E(\text{length of a cycle})}, \quad (11)$$

where the loss is defined as the total cost minus total revenue and a cycle is the time between two consecutive replacements.

Under the replacement policy T , denote the length of a cycle by W , then

$$W = T + V_n \text{ and } U_n < T \leq U_{n+1} \text{ for } n = 0, 1, \dots \quad (12)$$

From Definition 3 and Assumption 3, it follows that $E(Y_n) = \frac{\mu_{Y_1}}{r_b^{(n-1)}}$. Then,

$$\begin{aligned} E(W) &= E\left(T + \sum_{j=1}^n Y_j\right) \\ &= E\left[T + \sum_{j=1}^{\infty} Y_j I(n \geq j)\right], \end{aligned}$$

where I is the indicator random variable defined as

$$I(n \geq j) = \begin{cases} 1 & \text{if } n \geq j, \\ 0 & \text{if } n < j. \end{cases}$$

Since $n \geq j \Leftrightarrow U_j \leq T$, we have

$$\begin{aligned} E(W) &= E\left[T + \sum_{j=1}^{\infty} Y_j I(U_j \leq T)\right] \\ &= E(T) + \sum_{j=1}^{\infty} E(Y_j) E[I(U_j \leq T)] \\ &\quad \text{as } Y_j \text{ and } U_j \text{ are independent} \\ &= T + \sum_{j=1}^{\infty} \left(\frac{\mu_{Y_1}}{r_b^{(j-1)}}\right) [1 \times \Pr(U_j \leq T) \\ &\quad + 0 \times \Pr(U_j > T)] \\ &= T + \mu_{Y_1} \sum_{j=1}^{\infty} \frac{F_j(T)}{r_b^{(j-1)}}, \end{aligned}$$

where F_j is the distribution function of U_j .

Thus, from Equation (11) the long-run expected loss per unit total time $l(T)$ under policy T is given by

$$l(T) = \frac{(c_o - w)T + c_f \mu_{Y_1} \sum_{j=1}^{\infty} \frac{F_j(T)}{r_b^{(j-1)}} + c_{RT} u_{RT}}{T + \mu_{Y_1} \sum_{j=1}^{\infty} \frac{F_j(T)}{r_b^{(j-1)}} + u_R T}, \quad (13)$$

and also from Equation (11), the long-run expected loss per unit total time $l(N)$ under policy N is given by

$$l(N) = \frac{(c_o - w) \mu_{X_1} \sum_{j=1}^N \frac{1}{r_a^{(j-1)}} + c_f \mu_{Y_1} \sum_{j=1}^{N-1} \frac{1}{r_b^{(j-1)}} + c_{RN} u_{RN}}{\mu_{X_1} \sum_{j=1}^N \frac{1}{r_a^{(j-1)}} + \mu_{Y_1} \sum_{j=1}^{N-1} \frac{1}{r_b^{(j-1)}} + u_{RN}}. \quad (14)$$

In practice, we prefer to adopt the optimal policy N^* rather than use the optimal policy T^* , because of the much simpler form of $l(N)$. Moreover, under some mild conditions, Lam [37] proved that the optimal policy N^* is better than any policy T ; in particular, it is better than the optimal policy T^* .

To conclude this section, we mention two comprehensive reviews [38,39] of modeling some maintenance practices using GPs and statistical inference of model parameters, and a latest paper using the GP approach by Leung *et al.* [40].

Imperfect Preventive Maintenance

In many PM models, a system is assumed to be as good as new after each PM action. However, a more realistic situation is one in which the failure pattern of a preventively maintained system changes. One way to model this is to assume that, after PM, the ROCOF of the system is somewhere between as good (same) as new and as bad (same) as old. This concept is called *imperfect maintenance*.

To illustrate these types of models, consider the following PM policy proposed by Nakagawa [41]. PM is done at fixed intervals $x_k (k = 1, 2, \dots, N-1)$ and the system is replaced at the N th PM. If the system

fails between PMs, it undergoes only minimal repair. The PM is imperfect. The age after the k th PM reduces to $b_k t$, while it was t before PM (b_k is constant and $0 \leq b_k \leq 1$).

The problem is to find the optimal interval lengths $x_k (k = 1, 2, \dots, N-1)$ and the optimal number N of PMs when a replacement is done so that total expected cost rate is minimized. Let c_p be the cost of a scheduled PM, c_r be the cost of replacement, and c_m be the cost of minimal repair at failure. Also, let $r(t)$ denote the ROCOF function.

The imperfect PM model is developed under the following assumptions:

1. The age after the k th PM reduces to $b_k t$, while it was t before PM, that is, the system with age t becomes $t(1 - b_k)$ units of time younger at the k th PM, where $0 = b_0 < b_1 < \dots < b_N < 1$.
2. The system undergoes only minimal repair at failures between PMs. The ROCOF remains unchanged by minimal repair (by the definition of minimal repair).
3. The ROCOF function $r(t)$ is continuous and strictly increasing.
4. The times for PM, minimal repair, and replacement are negligible.
5. Time returns to zero after replacement, that is, the system is as good as new at replacement.

Let y_k be the effective age of the system immediately before the k th PM. Note that $y_k = x_k + b_{k-1} y_{k-1} (k = 1, 2, \dots, N)$. Hence, during the k th PM interval the age of the system changes from $b_{k-1} y_{k-1}$ to y_k . Note that $x_k = y_k - b_{k-1} y_{k-1}$.

It is more convenient to express the cost function in terms of y_k than in terms of x_k . The expected total cost per cycle is the sum of the expected cost of minimal repairs, the expected cost of PMs, and the cost of replacement. Thus,

$$E(C) = c_m \sum_{k=1}^N \int_{b_{k-1} y_{k-1}}^{y_k} r(t) dt + (N-1)c_p + c_r. \quad (15)$$

The expected cycle length is

$$E(T) = \sum_{k=1}^{N-1} (1 - b_k)y_k + y_N. \quad (16)$$

The problem is to find the optimal number N of PMs and the optimal interval lengths $x_k (k = 1, 2, \dots, N - 1)$ that minimize the total expected cost rate given by

$$C(y_1, y_2, \dots, y_N) = \frac{E(C)}{E(T)}. \quad (17)$$

Pham and Wang [42] provided a review of imperfect PM models. The reader is referred to this extensive review for more information on these models. In addition, some recent papers on imperfect PM modeling for a complex system with two dependent/independent failure modes: maintainable (e.g., the ROCOF of a mechanical component can be reduced by PM actions) and nonmaintainable (e.g., an electronic component) include Lin *et al.* [43], El-Ferik and Ben-Daya [44], Zequeira and Berenguer [45], Bartholomew-Biggs *et al.* [46], and Castro [47].

Condition-Based Maintenance

CBM consists of deciding whether or not to maintain a system according to its state using condition-monitoring techniques. There are three types of decisions that need to be made:

1. Selecting the parameters to be monitored. This depends on several factors such as the type of equipment and technology available.
2. Determining the inspection frequency.
3. Establishing the warning limits that trigger appropriate maintenance action, which could be static or dynamic.

Representative models for CBM, based on Cox's [48] proportional hazards (PH) model, are discussed here. Other modeling schemes such as the state space model and the Kalman filter for prediction [49] can also be used as modeling tools.

Cox's PH model differs from other models in the way the equipment reliability is estimated. In this case, equipment reliability is not estimated based only on its age as is usually the case. In addition to age, reliability is estimated also based on concomitant information such as the information obtained from condition-monitoring techniques (vibration analysis, oil analysis, etc.). Essentially the procedure is to modify the hazard function $h(x)$ by multiplying it by a function $g[z(x)]$ where $z(x)$ is the concomitant variable (sometimes called *covariate* or *explanatory variable*).

The PH model can be defined by

$$h(x) = h_0(x)g[z(x)] \text{ for } x \geq 0, \quad (18)$$

where $h_0(x)$ is called the *baseline hazard*, which is the hazard that the system would experience if the effects of all covariates are equal to zero.

A popular choice for the link function $g[z(x)]$ is the log-linear form

$$g[z(x)] = e^{\gamma z(x)}, \quad (19)$$

where γ is the regression coefficient. In fact, Cox's PH model is a multiple regression model. In the case of several covariates (several monitored variables), γ and $z(x)$ can be made vectors

$$h(x) = h_0(x)e^{\gamma_1 z_1(x) + \gamma_2 z_2(x) + \dots}. \quad (20)$$

The advantage of this method is that the hazard function is determined on the basis of both the age of equipment and its condition. This makes it very useful in a CBM context.

There are situations when the hazard increases with time. Then, it is reasonable to schedule a preventive replacement when the hazard becomes too high. To determine the optimal hazard level (threshold level), it is necessary to predict the future behavior of covariates. Makis and Jardine [50,51] assumed a widely accepted Markov process model to describe the stochastic behavior of covariates and presented optimal replacement decision models. One of these models was included in a CBM software package [52]. For more details, refer to Kumar and Klefsjo [53], Kumar [54], and Maillart [55].

Inspection

The inspection problem in maintenance tends to be centered around determining the optimal interval between checks on equipment to assess its status.

The problem of determining an optimal inspection policy has been widely discussed in the literature [2]. Two literature reviews of inspection are given in Leung [56] and Nakagawa [11, Chapter 8].

Some of these models combine inspection and replacement decisions. It is assumed that repairs at a modest cost will bring the production process to the in-control state. However, the residual life after these repairs will depend on the age of the system. After a certain number of repairs, replacement is performed. The problem is to determine an optimal inspection policy and the optimal replacement time that will minimize the expected cost per unit time. Models in these areas differ in the following features:

1. failure process mechanism (e.g., Markovian versus non-Markovian);
2. types of repair (e.g., minimal repairs);
3. Assumptions about inspection intervals (e.g., constant interval length and constant interval hazard).

Examples of this model include the work of Barlow and Proschan [9], Munford and Shahani [57], Munford [58,59], and Banerjee and Chiu [60].

Examples of models involving inspection decisions only include the work of Baker [61], Ben-Daya and Hariga [62], and Hariga [63]. More information on these models can be found in Hariga and Al-Fawzan [64]. In many cases, the inspection problem is jointly considered with repair and/or replacement decisions [65,66].

The other situation in which the inspection problem arises is when the purpose of the inspection is to find out whether the system has shifted to an out-of-control state, in which case a restoration action of the system to the in-control state is needed. Lee and Rosenblatt [67] considered an economic lot-sizing problem involving inspections aimed at assessing the status of the production process. In a

similar context, Rahim [68] and Ben-Daya [69] considered quality control inspections to assess the production system's status.

The inspection problem also arises in the context of CBM. As discussed earlier, CBM consists of deciding whether or not to maintain a system according to its state. The state of the system can be represented by an indicator variable that measures its deterioration. Once indicators, such as bearing wear and gauge readings, which are used to describe the state, have been specified, inspections are made to determine the values of these indicators. Appropriate maintenance action may then be taken, depending on the state. The state of the system is represented by the value taken by a random variable X . This random variable is observed at times t_i ($i = 1, 2, \dots$), and x_i is the value of X at time t_i . This variable is equal to zero if the system is new. The greater x_i , the closer the system is to a breakdown. The system breaks down if the value of X exceeds a given limit L . Taylor [70] proposed one of the earliest research works in this area. The model assumes that the system is subject to shocks that follow a Poisson distribution. The magnitude of system deterioration resulting from a shock follows an exponential distribution and the magnitudes of deterioration are independent of each other. The maintenance and repair costs are assumed to be constant. Under these assumptions, Taylor showed that the optimal policy is a control limit policy (CLP). In other words, there exists a limit x^* such that if the state of deterioration of the system is greater than x^* but less than a breakdown limit, then maintenance is required. However, no action is needed if the state of deterioration is below x^* .

Bergman [71] introduced a more general model in which the state of deterioration of the system is a nondecreasing random variable. He also proved that the CLP is an optimal policy. Zuckerman [72] provided the properties of the system (conditions) under which the CLP is optimal.

Several inspection models [73] use the delay-time concept. Delay time is defined as the time lapse from when a fault could first be noticed until the time when its repair can no longer be delayed because of unacceptable

failure consequences [74]. A repair can be undertaken during the delay-time period to avoid breakdown.

A basic delay-time inspection model is presented here. This model is based on the following assumptions:

1. The probability density function $f(h)$ of the delay time h is known.
2. Inspections take place at regular intervals of time of equal length T ; each inspection costs c_i and its duration is d_p .
3. Inspections are perfect.
4. The time of origin of the fault is uniformly distributed over time since the last inspection and is independent of h .
5. Faults arise at the rate of λ per unit time.
6. A breakdown repair costs c_f and has an average duration d_f , and an inspection repair costs c_p and has an average duration d_p .

The problem is to determine the length of the inspection interval T that minimizes the expected cost or downtime rate.

Suppose that a fault arising in the interval $(0, T)$ has a delay time in the interval $(h, h + dh)$ with probability $f(h)dh$. A breakdown repair will be performed if the fault arises in the interval $(0, T - h)$, otherwise an inspection repair will be carried out. The probability that the fault arises before $(T - h)$, given that a fault will occur, is $\frac{T-h}{T}$ (because of Assumption 4). The probability of a breakdown repair is given by

$$p(T) = \int_0^T \frac{T-h}{T} f(h) dh. \quad (21)$$

The expected downtime rate $D(T)$ is given by

$$D(T) = \frac{\lambda T d_f p(T) + d_p}{T + d_p}. \quad (22)$$

The expected cost rate $C(T)$ is given by

$$C(T) = \frac{\lambda T \{c_f p(T) + c_p [1 - p(T)]\} + c_i}{T + d_p}. \quad (23)$$

These models have been used in preventive maintenance, condition monitoring, and other settings. For a review of delay-time models, the reader is referred to the papers by Baker and Christer [75], Christer [73], and Wang [76].

RISK ASSESSMENTS AND BLACK SWANS

TERJE AVEN

Department of Industrial
Economics, Risk Management,
and Planning, University of
Stavanger, Stavanger, Norway

INTRODUCTION

Risk assessments are based on probabilities and probability models. On the basis of these probabilities and models, assessments and predictions of unknown quantities are made. The probabilities and models are, to a large extent, based on the historical data observed. Such assessments have been used successfully in many types of industries, for example, nuclear and oil and gas. However, in the case of large uncertainties, the quality of these tools has been questioned. Probability models are difficult to justify and the probability estimates are subject to large uncertainties. It is acknowledged that a probability is not a “perfect tool” for measuring uncertainties: The assigned probabilities are conditional on specific background knowledge, which includes assumptions and suppositions. This knowledge could be poor, and the assumptions and suppositions may turn out to be erroneous, the result being that the probabilities assigned lead to poor predictions. Surprises relative to the assigned probabilities may occur; and by just addressing the probabilities, such surprises may be overlooked.

Let us look at an example. Consider the risk, seen through the eyes of a risk analyst in the 1970s, related to future health problems for divers working on offshore petroleum projects. An assignment is to be made for the probability that a diver would experience health problems (properly defined) during the coming 30 years due to the diving activities. Let us assume that an assignment of 1% is

made. This number is based on the available knowledge at that time. There are no strong indications that the divers will experience health problems. However, we know today that these probabilities led to poor predictions. Many divers have experienced severe health problems ([1], p. 7). By restricting risk to the probability assignments alone, we see that aspects of uncertainty and risk are hidden. There is a lack of understanding about the underlying phenomena, but the probability assignments alone are not able to fully describe this status.

Taleb [2] draws a similar conclusion using black swan logic. The inability to predict outliers (black swans) implies the inability to predict the course of history. An outlier lies outside the realm of regular expectations, because nothing in the past can convincingly point to its occurrence. The standard probabilistic methods and models used for analyzing uncertainties are not able to predict black swans.

These standard methods are suitable when there are more relevant data available. To apply the methods, probability models such as the normal distribution and the linear regression model need to be specified. The analysis is based on the assumption of a specific distribution and a specific trend curve (for example linear), which governs the future performance. But it is by no means obvious what the appropriate distribution and model should be. No one knows about the future. The historical data may indicate a specific distribution and a trend, more or less excluding extreme observations, but this does not preclude such observations occurring in the future. Statistical analysis is based on the idea of a huge number of similar situations and if “similar” is limited to the historical data, the population considered could be far too small. However, the statistician needs models to be able to perform the statistical analysis, and he/she will base his/her analysis on the data available. Taleb [2] refers to the world of *mediocristan* and *extremistan* to explain the

difference between the standard probability model context and the more extended population required to reflect surprises that occur in the future, respectively. Without explicitly formulating the thesis, Taleb [2] says that we have to see beyond the historical-based probability models, to be able to adequately reflect future observations.

The standard methods focus on the parameters, for example, $\mu_i = \alpha + i\beta$ in regression analysis. But why be concerned about μ_i , the average value when considering an infinite number of similar activities to the one studied? Risk is about the possible occurrence of surprise, and in particular negative outcomes in the future. An analysis that focuses on averages fails to reveal this in two ways:

1. The key quantity of interest is the outcome Y (e.g., future cost, number of fatalities, etc.), but the standard analysis does not express uncertainties about Y . Instead, uncertainties are expressed about fictional parameters, such as EY interpreted as the average value of Y when considering an infinite number of similar activities to the one studied.
2. The analysis is, to a large extent, based on the historical data and models explaining these, and gives little weight to possible extreme observations. The data may be more or less relevant for the future.

Some would respond to this by stating that using the historical data is the best we can do, and the analysis must always be seen in relation to its assumption. The analysis provides insights, although the assumption may be invalid. An analysis must always be seen in the light of its assumptions, but to fully express risk we can and should do better than restrict attention to historical data and estimate averages.

Many researchers have addressed the problem of using risk assessment in the case of large uncertainties [3–5]. Reid [3] argues that the claims of objectivity in risk assessments are simplistic and unrealistic. Risk estimates are subjective, and there is a common tendency of underestimation of the

uncertainties. According to Stirling [6], using risk assessment when strong knowledge about the probabilities and outcomes does not exist, is irrational, unscientific, and potentially misleading. Renn [5] summarizes the critique drawn from the social sciences over many years and concludes that technical risk analyses represent a narrow framework that should not be the single criterion for risk identification, evaluation, and management.

The answer to this type of critique is, according to O'Brien [7], to look for an alternative to risk assessments. But in our view there is no alternative to risk assessments. The critique of risk assessment is to a large extent justified, but to support the decision making we need to assess risk. The right move forward is not to reject risk assessment, but to improve the tool and its use. This also seems to be the conclusion made by most researchers in the field. The challenge is how decision making on risk can be informed by the best available technical and scientific knowledge [4, p. 100; 8]. To represent and describe this knowledge, judgments about uncertainties are required. Properly conducted risk assessments make these judgments visible and explicit. For the present study we are particularly concerned about the ability of the risk assessments to describe risk contributions from potential surprises (black swans). As argued above, the traditional probabilistic-based analysis has too narrow a risk perspective and should be replaced by a broader uncertainty characterization.

Uncertainty is a frequently occurring topic in risk assessment research, but its scope is often very technical. The literature is characterized by some prevailing ways of thinking on how to deal with uncertainties in risk assessments [9]. We seldom see fundamental discussion about uncertainty in a risk assessment context that extends beyond this thinking. It is acknowledged that risk assessments provide decision support—the decisions are risk-informed and not risk-based [8]—but what are the key aspects to consider outside the realm of the traditional risk assessment results? We argue in this article for the need for assessing

uncertainty factors that are “hidden” in the background knowledge of the assigned probabilities and expected values. The results of the risk assessments must be extended beyond the probabilistic world. In line with this thinking, we must also redefine the concept of risk: uncertainty should replace probability in the definition of risk. The common definitions of risk in the contexts we address in this article are based on the probabilities of events and their consequences [10]. In this article, we describe a framework for such extended risk assessments. But first we give a brief review of the basic features of risk assessment.

BASIC FEATURES ABOUT RISK ASSESSMENTS

In risk assessment we study an activity that may lead to events A with consequences C . Think of A as, for example, the occurrence of a gas leakage or an attack, and C as the consequences of A with respect to human life, the environment, and other attributes that humans value, measured, for example, by the number of fatalities. The consequences may take values in a space S when such a space can be formulated. The occurrence of A and the consequences C are subject to uncertainties U . Probability P is used as a measure of the uncertainties. To make this setup more precise, we need to clarify what we mean by U and P .

First, we need to clarify what we are uncertain about. Is it about aspects of the world expressed by quantities (A, C) ? Or, are the uncertainties related to the uncertainties about the world and the risk description? See Fig. 1. In the latter case, relative

frequency-interpreted probabilities (chances) p are used to describe the risk related to A and C . The probabilities (chances) express variations within mentally constructed infinite populations.

To respond to these questions, we consider two possible objectives of the risk assessments: The purpose of the risk assessment is to (i) accurately estimate the risk, that is, the probabilities (chances) p ; or (ii) to describe the uncertainties about the world (Fig. 2).

The Objective of the Risk Assessment is to Accurately Estimate the Risk (Probabilities)

Suppose that a risk assessment investigates the probability p of an accidental event A . The probability p is defined as the fraction of times the accidental event A occurs if the activity considered were repeated (hypothetically) an infinite number of times. It expresses variations within this mentally constructed infinite population. Since the true value of p is unknown, it must be estimated. The estimation accuracy (precision) can be described in different ways, but the common tool is confidence intervals. If we have a substantial amount of data available and these are considered relevant for the estimation of the statistical parameters p , that is, the observations are considered similar to those of the population generating p , statistical theory shows that the estimation error becomes negligible. However, in a practical risk assessment setting, data are often scarce. If the statistical analysis is based on few data, the estimation accuracy would be poor and the confidence intervals would be wide. Hence, if the goal of the risk assessment is to obtain

Figure 1. Illustration of the issue: what is uncertain in risk assessments? Here A and C are events and their associated consequences, and p frequentist probabilities (chances) linked to A and C .

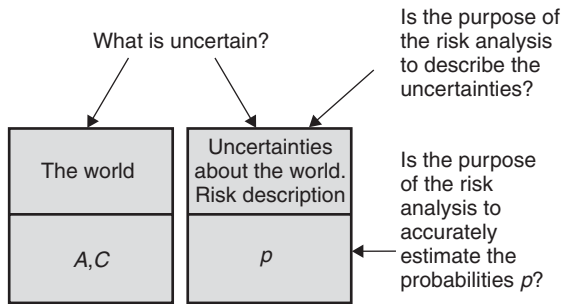

Figure 2. Different aims of the risk assessment.

accurate estimates of some true risk, we can quickly conclude that risk assessment fails. The uncertainties are, in practical cases, often large.

To increase the amount of data, we often extend the relevant population of observations to cover situations that to a varying degree are similar to the one being studied. This reduces the quality, that is, the relevancy of the data, but it would not be possible to describe this aspect by the statistical analysis. If the data are not considered relevant, the statistical analysis cannot be used to check whether the produced risk numbers are accurate compared to the underlying true risk.

Hence, we can focus on risk assessments being a tool to describe uncertainties.

The Objective of the Risk Assessment is to Describe our Uncertainties about the World

For many activities, there are large uncertainties about the world, about the occurrence of events and their consequences, as well as about the underlying factors that cause these events and consequences to occur. The aim of the assessment is to describe these uncertainties. This means that we have to (i) identify what is uncertain and (ii) who is uncertain.

Often, we are able to reduce (i) to a set of quantities, such as the occurrence of events, and the number of fatalities. We denote these events by A and the quantities by C . In most cases, in a risk assessment the answer to (ii) is the analysts. However, in some situations it could be essential to present different uncertainty assessments reflecting the different views among experts and various

stakeholders. Integrating all views into one aggregated figure could camouflage important aspects of the risk picture.

Next, we address the issue on how to express the uncertainties. Probability is the common tool, but a probability has different interpretations.

However, to describe the uncertainties, only one interpretation is suitable: the probabilities must be knowledge-based (subjective) probabilities with reference to a standard expressing the analysts' uncertainty about A and C . Following this interpretation, the assessor compares his/her uncertainty about the occurrence of the event A with the standard of drawing at random a favorable ball from an urn that contains $P(A) \cdot 100\%$ favorable balls.

Relative frequency interpreted probabilities (chances) p are not measures of uncertainty. They exist as proportions of infinite or very large populations of similar units to those considered. They are treated as unknown quantities C .

The knowledge-based probabilities express *epistemic uncertainties*. The variation in the populations of similar units to the one (those) studied that, for example, generates the true value of p , is often referred to as *aleatory (stochastic) uncertainty*. This uncertainty is, however, not an uncertainty for the analysts.

But a knowledge-based (subjective) probability can be given different interpretations: the betting interpretation and the reference to a standard defined above. Among economists and decision analysts, and the earlier probability theorists, a subjective probability is linked to betting: the probability of an event is the price at

which the person assigning the probability is neutral between buying and selling a ticket that is worth one unit of payment if the event occurs, and worthless if not [11].

But this interpretation is not appropriate to describe uncertainties as it extends beyond the realm of uncertainty assessments—it reflects the assessor's attitude to money and the gambling situation, which means that the analysis (evidence) is mixed with values. The scientific basis for risk assessment is founded on the idea that professional analysts describe risk separated from how we (the assessor, the decision maker, or other stakeholders) value the consequences and the risk.

Different probability-based measures are used to describe risk, such as probability distributions, the expected value, the variance, and quantiles. If relevant data are available, these data are used as the basis for the assignments of these measures. Models are often introduced to ease the assignments, in particular, probability models. The probability models coherently and mechanically facilitate the assignments and updating of probabilities. A Bayesian framework is adopted allowing both hard data and expert judgment to be taken into account in the assessment.

But a full risk description needs to see beyond these P measures. All probabilities are conditional on a background knowledge

K , which includes assumptions and suppositions, and in particular, the models used in the assessment. This background knowledge is an integral part of the results of the analysis and all probabilities need to be considered in relation to K . We explain this in more detail in the coming section.

A FRAMEWORK FOR AN EXTENDED RISK AND UNCERTAINTY ASSESSMENT

In this section, we present a framework for risk assessment that highlights uncertainties and in this way the potential for surprises (black swans). The framework is based on Aven [12].

Figure 3 presents the overall risk assessment framework. The key quantities of interest are denoted Z . To assess Z , a model $G(X)$ is introduced, which links a set of input quantities X to Z . Using the model G , an uncertainty description is obtained for Z . The tool used for this purpose could be an analytical approach or Monte Carlo simulation.

The framework is based on the building blocks summarized in the section titled “The Objective of the Risk Assessment is to Describe our Uncertainties about the World.” Hence, all probabilities are knowledge-based (subjective) probabilities with reference to a standard. The framework is based on a

Figure 3. Structure of the suggested framework [12].

risk perspective, where the risk concept captures both consequences and uncertainties [12–14].

In addition to the probability-based measures, the framework requires a separate identification and assessment of uncertainty factors. These factors are generated from the background knowledge K and in particular the assumptions made.

The uncertainty assessments of these factors could, for example, take the following form [12,13]: Each factor's importance is measured using a sensitivity analysis. Is changing the factor important for the risk indices considered, for example, the probability that the loss exceeds a specific number? If this is the case, we next address the uncertainty of this factor. Are there large uncertainties about this factor? If the uncertainties are assessed as large, the factor is given a high risk score. Hence, to obtain a high score in this system, the factor must be judged as important for the risk indices considered and the factor must be subject to large uncertainties. This uncertainty assessment goes beyond the probabilistic analysis.

As an example, think of an assessment related to a process plant that is based on the following assumptions:

- The use of a gas leakage database L that includes data from plants operated under quite different operating conditions than the one considered.
- The use of a new technology for operating a system (S) is not changing the overall performance of the system compared to average industry data.

From this list we identify two uncertainty factors:

1. the number of gas leakages,
2. the performance of the system S .

An assessment of these factors is performed according to the ideas outlined above. The risk indices are sensitive to changes in these factors, and both factors are subject to considerable uncertainties. Special concern is related to the use of the database L , and based on the risk evaluation it was decided to

look closer into this factor and try to reduce the uncertainties and avoid surprises.

In the uncertainty evaluation, a broad uncertainty description is provided, covering probabilities, related background knowledge, and the results from sensitivity analyses, as well as the assessment results for the uncertainty factors. The evaluation provides input to a broader managerial review and judgment, which concludes on the implications of the analysis and balances different concerns (e.g., safety and costs). The result is, for example, an acceptance of the risk and uncertainties related to an activity, the need for design changes, the choice of an alternative, and so on.

It is common in risk assessments to compare the results of the assessments with relevant decision criteria, such as requirements of the form $P < p_0$, where p_0 is a fixed number [1,15]. These requirements could, for example, express that the unreliability level of a system should not exceed a specified level.

Now, given that P is a knowledge-based probability, we cannot base our decision on a direct comparison of the form $P < p_0$. There is a need for a process that extends beyond the probabilistic analysis. The probabilities are dependent on the background knowledge, the assumptions, and suppositions made, including the model G . What is required is a broader process, an uncertainty evaluation and management review and judgment, which sees the results of the assessment in a larger context, taking into account the limitations of the model, the difficulties in specifying probabilities for some quantities, and so on. This process extends beyond the domain of the traditional probability-based uncertainty analysis. The sensitivity analyses constitute an important input to a broad review and judgment process.

DISCUSSION AND CONCLUSIONS

The historical data provides insights about risk. Assuming that the future will be as the history shows, we may obtain good predictions about the future. However, there is in principle, a huge step from the history to risk, as any assumption transforming the

data to the future may be challenged. To fully express risk, we need to look beyond the historical-based data. Care should be shown when using traditional statistical analysis to describe risk, as this analysis is based on strong assumptions. Risk is, to a large extent, about the aspects not included in such analyses, namely surprises. Risk assessments go one step further by identifying hazards/threats/scenarios that could happen, not necessarily based on historical data. Many techniques have been developed to reveal such hazards/threats/scenarios and analyze and describe the associated risk. Probabilities are used to quantify the likelihood and uncertainties of the events and consequences identified. However, these analyses are not particularly suited for revealing surprises, as discussed above. The black swans are often hidden in the background knowledge of the assessments. To highlight these we suggest an approach that extends the traditional probabilistic analysis to include assessment of uncertainty factors. What we suggest is a broad risk assessment of the uncertainty factors, not a detailed quantitative risk assessment but a more qualitative approach. Crude probabilities may be assigned for the uncertainty factors but these do not replace the qualitative judgments. The search for quantitative, explicit approaches for expressing the uncertainties, even beyond the knowledge-based (subjective) probabilities, may seem to be a possible way forward. However, such an approach is rejected. Trying to be precise and accurately expressing what is extremely uncertain does not make sense. Instead, we recommend a more open qualitative approach for revealing such uncertainties, as described above.

Such an approach would not be able to guarantee that all surprises would be identified. However, the approach provides a framework for highlighting uncertainties. By seeing beyond the probabilities, an extended search basis is established. Some decision makers, managers, and politicians may find this approach unattractive as it means that the decision basis gives less clear answers. The decision maker has to weigh

the uncertainties and balance them against other concerns, such as profit. For some this would be hard. They expect science to be able to produce clear answers. But science cannot eliminate the uncertainties. The challenge is, therefore, to reveal the uncertainties to obtain an improved decision basis. The presented framework provides guidance on how to obtain such a basis.

PORTFOLIO SELECTION PROBLEM

Let us consider the following portfolio selection problem. Suppose that we want to invest capital W_0 in n assets, by investing an amount x_i in asset i , for $i = 1, \dots, n$. Suppose, further, that each asset has a respective return rate R_i . We address now the question of how to distribute our wealth W_0 in an optimal way. The total wealth resulting from our investment, after one period of time, is $W_1 = W_0 + R^\top x$, where $R = (R_1, \dots, R_n)^\top$ and $x = (x_1, \dots, x_n)^\top$ are the respective (column) vectors and $R^\top x = \sum_{i=1}^n R_i x_i$ is their scalar product (for the sake of simplicity we do not take into account here the transaction costs). The problem is that at the time we have to make the investment decision, the return rates R_i are *unknown*.

Suppose that we can model the unknown returns R_i as random variables, and hence to consider their expected values $\bar{r}_i := \mathbb{E}[R_i]$, $i = 1, \dots, n$ (the notation “ $:=$ ” means equal by definition). Then we can try to maximize the expected return on an investment subject to the budget constraint $\sum_{i=1}^n x_i = W_0$. This leads to the following optimization problem

$$\text{Max}_{x \geq 0} \mathbb{E}[W_1] \text{ subject to } \sum_{i=1}^n x_i = W_0. \quad (1)$$

Since $\mathbb{E}[R^\top x] = \sum_{i=1}^n \bar{r}_i x_i$, Problem (1) has a simple optimal solution of investing everything into an asset with the largest expected return rate $\max_{1 \leq i \leq n} \bar{r}_i$. Of course, from the practical point of view, such a solution of

putting everything into one asset is too risky.

There are several ways how one can try to control the risk by making a more even distribution of the wealth among n assets. One approach is to maximize expected utility of the wealth represented by a concave nondecreasing function $U(\cdot)$. This leads to the problem of maximizing $\mathbb{E}[U(W_1)]$ subject to the “no borrowing” constraint $x \geq 0$ and the budget constraint. This approach requires specification of the utility function $U(\cdot)$, which could be quite arbitrary and not very intuitive. It could also be noted that calculation of the expectation $\mathbb{E}[U(W_1)]$ requires specification (knowledge) of the probability distribution of the random vector R , while $\mathbb{E}[W_1]$ involves only the first-order moments of the random returns.

Another possible approach is to maximize the expected return while controlling the involved risk of the investment. There are several ways how the concept of risk could be formalized. For instance, we can evaluate risk by variability of W_1 measured by its *variance* $\text{Var}[W_1]$. Since W_1 is a linear function of the random variables R_i , we have that $\text{Var}[W_1] = x^\top \Sigma x$, where Σ is the covariance matrix of the random vector R . This leads to the optimization problem of maximizing the expected return subject to the additional constraint $\text{Var}[W_1] \leq \nu$, where $\nu > 0$ is a specified constant. This problem can be written as

$$\begin{aligned} & \text{Max}_{x \geq 0} \sum_{i=1}^n \bar{r}_i x_i, \\ & \text{subject to } \sum_{i=1}^n x_i = W_0, \quad x^\top \Sigma x \leq \nu. \end{aligned} \quad (2)$$

Since the covariance matrix Σ is positive semidefinite, the function $x \mapsto x^\top \Sigma x$ is convex quadratic, and hence Equation (2) is a convex problem.

By duality arguments there exists Lagrange multiplier $\lambda \geq 0$ such that Problem

(2) is equivalent to the problem

$$\begin{aligned} & \text{Max}_{x \geq 0} \sum_{i=1}^n \bar{r}_i x_i - \lambda x^\top \Sigma x, \\ & \text{subject to } \sum_{i=1}^n x_i = W_0. \end{aligned} \quad (3)$$

We can view the objective function of the above Problem (3) as a compromise between the expected return and its variability measured by its variance. This approach was suggested by Markowitz [1], more than 50 years ago, and is still routinely used in portfolio selections.

Let us make the following observations. Problem (3) is a (convex) quadratic programming problem for which efficient numerical algorithms are available (such algorithms were already available in 1952, the time of publication of Markowitz [1] paper). Problem (2) is a convex conic programming problem which also can be efficiently solved by modern interior point algorithms. Both Problems (2) and (3) do not require specification of the whole probability distribution of the random vector R , only its first- and second-order moments. It is also worthwhile to mention that Problems (2) and (3) depart from Problem (1) in that these problems utilize possible correlations between random returns of different assets.

Let us point now to the following conceptual deficiencies of Markowitz's approach. The variance, as a measure of risk, penalizes deviations from the average (expected value) in both directions—positive and negative. However, we are not really concerned here if a random realization of the return is bigger than the average; we do not want it to be significantly smaller. The other deficiency is that the function $\rho(W) := \mathbb{E}[W] - \lambda \text{Var}[W]$, of random variable W , is not necessarily monotone for $\lambda > 0$. That is, it can happen that for any possible realization of two random variables W and W' (defined on the same probability space), variable W is always bigger than W' while $\rho(W)$ is smaller than $\rho(W')$. This could lead to a paradoxical situation when for two different decision vectors x and x' any realization of the random return $R^\top x$

is bigger than $R^\top x'$, and yet we prefer x' as a solution of Problem (3).

We can also approach risk control by imposing chance constraints. Consider the problem

$$\begin{aligned} & \text{Max}_{x \geq 0} \sum_{i=1}^n \bar{r}_i x_i, \\ & \text{subject to } \sum_{i=1}^n x_i = W_0, \text{ Prob}\{R^\top x \leq b\} \leq \alpha. \end{aligned} \quad (4)$$

That is, we impose the additional constraint that probability of the return falling below a chosen constant b is small, that is, is no more than the specified level $\alpha \in (0, 1)$. Such constraints are called *chance* or *probabilistic* constraints.

Suppose, for the moment, that vector R of random returns has a multivariate normal distribution with mean vector $\bar{r}$ and covariance matrix Σ . Then $R^\top x$ has normal distribution with mean $\bar{r}^\top x$ and variance $x^\top \Sigma x$. Consequently, if $x^\top \Sigma x \neq 0$, then

$$\text{Prob}\{R^\top x \leq b\} = \Phi\left(\frac{b - \bar{r}^\top x}{\sqrt{x^\top \Sigma x}}\right), \quad (5)$$

where $\Phi(\cdot)$ is the cumulative distribution function of the standard normal distribution. Therefore, we can write the chance constraint of Problem (4) in the form

$$b - \bar{r}^\top x + z_\alpha \sqrt{x^\top \Sigma x} \leq 0, \quad (6)$$

where $z_\alpha := \Phi^{-1}(1 - \alpha)$ is the $(1 - \alpha)$ -quantile of the standard normal distribution (for example, $z_{0.025} = 1.96$). The function $x \mapsto \sqrt{x^\top \Sigma x}$ is convex, and if $\alpha \leq 0.5$, then $z_\alpha \geq 0$, and hence the Constraint (6) is convex.

The Constraint (6) can be interpreted as that the ratio $\frac{\bar{r}^\top x - b}{\sqrt{x^\top \Sigma x}}$ of the expected return minus b to the standard deviation of the return, should be not smaller than the (positive) constant z_α . It was possible to write the chance constraint of the Problem (4) in the closed form (Eq. 6) because of the assumption that distribution of R is normal. In general, it

could be quite difficult to handle such chance constraints numerically.

COHERENT RISK MEASURES

It was argued in the previous section that in some situations the approach of optimizing the random objective on average could be too risky. This raises the question of what could be a good measure of risk of a random variable. In order to formalize this problem we proceed as follows. Consider a sample space $(\Omega, \mathcal{F})$, equipped with sigma algebra $\mathcal{F}$, and a set (space) $\mathcal{Z}$ of $\mathcal{F}$ -measurable functions $Z : \Omega \rightarrow \mathbb{R}$. For instance, if the set Ω is finite, we can equip it with sigma algebra of all its subsets. In that case any real valued function $Z(\omega)$, $\omega \in \Omega$, is $\mathcal{F}$ -measurable and we can take $\mathcal{Z}$ to be the space of all functions $Z : \Omega \rightarrow \mathbb{R}$. In general, the space of all $\mathcal{F}$ -measurable functions could be too large for a meaningful development of the theory, we will discuss this later.

With random variable $Z \in \mathcal{Z}$ we associate a number $\rho(Z)$ called its *risk measure*. That is, risk measure is a mapping $\rho : \mathcal{Z} \rightarrow \mathbb{R}$ from the space $\mathcal{Z}$ into the real line. It is also possible to consider risk measures which can take values $+\infty$ or $-\infty$ as well. We avoid this by making a suitable choice of the space $\mathcal{Z}$ and assume that $\rho(Z)$ is real valued. An example of risk measure is

$$\rho(Z) := \mathbb{E}[Z] + \lambda \text{Var}[Z]. \quad (7)$$

This risk measure was used in the formulation (Eq. 3) of the portfolio selection problem. For the sake of notational convenience, we deal from now on with minimization, rather than maximization, formulations of optimization problems, therefore the constant λ in Equation (7) is assumed to be non-negative.

Few remarks are now in order. The term *risk measure* is somewhat misleading. It could be more appropriate to call it “mean-risk measure,” since it typically involves a compromise between minimizing the mean (expectation) and controlling variability of the objective function. Some authors use the term *acceptability functionals* [2]. Anyway,

the terminology of *risk measures* became standard, so we will follow it here.

Another question is what space $\mathcal{Z}$ to use. In order for the expectation $\mathbb{E}[Z]$ and variance $\text{Var}[Z]$ to make sense, we need to equip the sample space $(\Omega, \mathcal{F})$ with a probability measure P . Then we can consider the space $\mathcal{Z} := L_2(\Omega, \mathcal{F}, P)$ of all random variables Z with finite second-order moments. In that case, the risk measure $\rho(Z)$ defined in Equation (7), is finite valued for all $Z \in \mathcal{Z}$. In the subsequent analysis, we assume that $\mathcal{Z} := L_p(\Omega, \mathcal{F}, P)$ with $p \in [1, +\infty)$, that is, $\mathcal{Z}$ is the space of random variables, defined on the probability space $(\Omega, \mathcal{F}, P)$, with finite p th order moments. Note that $\mathcal{Z} = L_p(\Omega, \mathcal{F}, P)$ is a linear space, and equipped with the norm $\|Z\|_p := (\int_{\Omega} |Z(\omega)|^p dP(\omega))^{1/p}$ becomes a Banach space.

We refer to P as the *reference* probability measure. If $Z, Z' \in \mathcal{Z}$ and $Z(\omega) \geq Z'(\omega)$ for P -almost every $\omega \in \Omega$, we write this as $Z \succeq Z'$. Unless stated otherwise, we assume that the expectations, such as $\mathbb{E}[Z]$, are taken with respect to the reference probability measure P . In case of doubt, we write $\mathbb{E}_P[Z]$ to emphasize what probability measure is employed.

It was suggested in Ref. 3 that a “good” risk measure should satisfy the following axioms, and such risk measures were called *coherent*.

- (A1) *Monotonicity*: If $Z, Z' \in \mathcal{Z}$ and $Z \succeq Z'$, then $\rho(Z) \geq \rho(Z')$.
- (A2) *Convexity*:

$$\rho(tZ + (1-t)Z') \leq t\rho(Z) + (1-t)\rho(Z')$$

for all $Z, Z' \in \mathcal{Z}$ and all $t \in [0, 1]$.

- (A3) *Translation Equivariance*: If $a \in \mathbb{R}$ and $Z \in \mathcal{Z}$, then $\rho(Z + a) = \rho(Z) + a$.
- (A4) *Positive Homogeneity*: If $t > 0$ and $Z \in \mathcal{Z}$, then $\rho(tZ) = t\rho(Z)$.

We already argued in the previous section that the monotonicity property (axiom A1) is a natural condition that a risk measure should satisfy. Convexity property is also a natural one. Because of (A4) the convexity property (A2) holds iff $\rho(Z + Z') \leq \rho(Z) + \rho(Z')$ for all $Z, Z' \in \mathcal{Z}$. That is, risk of the sum

of two random variables is not bigger than the sum of risks. Axioms (A3) and (A4) postulate position and scale properties, respectively, of risk measures.

The risk measure ρ defined in Equation (7) with $\lambda \geq 0$, satisfies axioms (A2) and (A3), but not (A1) and (A4) unless $\lambda = 0$. If the variance $\text{Var}[Z]$ in the definition of that risk measure is replaced by the standard deviation $\sqrt{\text{Var}[Z]}$, then the property (A4) will also hold, but not the monotonicity property (A1). Another example of risk measure, popular in financial engineering, is the so-called value-at-risk measure

$$\begin{aligned} \text{V@R}_\alpha(Z) &:= \inf \{t : \text{Prob}(Z \leq t) \geq 1 - \alpha\} \\ &= F^{-1}(1 - \alpha), \end{aligned} \quad (8)$$

where $F(t) := \text{Prob}(Z \leq t)$ is the cumulative distribution function of Z . That is, $\text{V@R}_\alpha(Z)$ is the left side $(1 - \alpha)$ -quantile of the distribution of Z . This risk measure satisfies axioms (A1), (A3), and (A4), but not (A2). We will discuss examples of coherent risk measures later.

We have the following basic duality result associated with coherent risk measures. With each space $\mathcal{Z} := L_p(\Omega, \mathcal{F}, P)$, $p \in [1, +\infty)$, is associated its dual space $\mathcal{Z}^* := L_q(\Omega, \mathcal{F}, P)$, where $q \in (1, +\infty]$ is such that $1/p + 1/q = 1$. For $Z \in \mathcal{Z}$ and $\zeta \in \mathcal{Z}^*$ their scalar product is defined as

$$\langle Z, \zeta \rangle := \int_{\Omega} Z(\omega) \zeta(\omega) dP(\omega). \quad (9)$$

We denote by

$$\mathfrak{P} := \left\{ \zeta \in \mathcal{Z}^* : \int_{\Omega} \zeta(\omega) dP(\omega) = 1, \zeta \geq 0 \right\} \quad (10)$$

the set of probability density functions in the dual space $\mathcal{Z}^*$.

Theorem 1. *Let $\mathcal{Z} := L_p(\Omega, \mathcal{F}, P)$ and $\rho : \mathcal{Z} \rightarrow \mathbb{R}$ be a coherent risk measure. Then ρ is continuous (in the norm topology of $\mathcal{Z}$) and there exists a bounded convex set $\mathfrak{A} \subset \mathfrak{P}$ such that*

$$\rho(Z) = \sup_{\zeta \in \mathfrak{A}} \langle Z, \zeta \rangle, \quad \forall Z \in \mathcal{Z}. \quad (11)$$

Conversely if the representation (Eq. 11) holds for some nonempty bounded convex set $\mathfrak{A} \subset \mathfrak{P}$, then ρ is a (real valued) coherent risk measure.

The dual representation (Eq. 11) follows from the classical Fenchel–Moreau Theorem [4]; in a certain form it was derived directly in Ref. 3. The present formulation is taken from Ref. 5. Note that for $\zeta \in \mathfrak{P}$ the scalar product $\langle Z, \zeta \rangle$ can be understood as the expectation $\mathbb{E}_Q[Z]$ taken with respect to the probability measure $dQ = \zeta dP$. Therefore, the representation (Eq. 11) can be written as

$$\rho(Z) = \sup_{Q \in \mathfrak{Q}} \mathbb{E}_Q[Z], \quad \forall Z \in \mathcal{Z}, \quad (12)$$

where $\mathfrak{Q} := \{Q : dQ = \zeta dP, \zeta \in \mathfrak{A}\}$.

Let us consider some examples. The following risk measure is called the *mean upper-semideviation risk measure* of order $p \in [1, +\infty)$:

$$\rho(Z) := \mathbb{E}[Z] + \lambda \left(\mathbb{E} \left[[Z - \mathbb{E}[Z]]_+^p \right] \right)^{1/p}, \quad (13)$$

where we use notation $[a]_+ := \max\{0, a\}$. In the second term of the right-hand side of Equation (13), the excess of Z over its expectation is penalized (recall that we deal here with minimization formulation of optimization problems). In order for this risk measure to be real valued it is natural to take $\mathcal{Z} := L_p(\Omega, \mathcal{F}, P)$. It is possible to show [6, Section 6.3.2] that for any $\lambda \in [0, 1]$ this risk measure is coherent and has the dual representation (Eq. 11) with the set

$$\begin{aligned} \mathfrak{A} &= \{ \zeta' \in \mathcal{Z}^* : \zeta' = 1 + \zeta - \mathbb{E}[\zeta], \\ &\quad \|\zeta\|_q \leq \lambda, \zeta \geq 0 \}. \end{aligned} \quad (14)$$

Another example of coherent risk measure is the conditional value-at-risk measure [7]

$$\begin{aligned} \text{CV@R}_\alpha(Z) &:= \inf_{t \in \mathbb{R}} \left\{ t + \alpha^{-1} \mathbb{E}[Z - t]_+ \right\}, \\ \alpha &\in (0, 1). \end{aligned} \quad (15)$$

It is natural to take here $\mathcal{Z} := L_1(\Omega, \mathcal{F}, P)$. This risk measure is also known under the names average value-at-risk, expected short-fall, and expected tail loss; these names are

motivated by Formulas (16) and (17) below. It is possible to show that the set of minimizers of the right-hand side of Equation (15) is formed by $(1 - \alpha)$ -quantiles of the distribution of Z , in particular, $t^* = V@R_\alpha(Z)$ is such a minimizer, and hence $CV@R_\alpha(Z) \geq V@R_\alpha(Z)$.

The conditional value-at-risk can be also written as

$$CV@R_\alpha(Z) = \frac{1}{\alpha} \int_0^\alpha V@R_\tau(Z) d\tau, \quad (16)$$

and, moreover, if the cumulative distribution function $F(t)$ of Z is continuous at $t^* = V@R_\alpha(Z)$, then

$$\begin{aligned} CV@R_\alpha(Z) &= \frac{1}{\alpha} \int_{V@R_\alpha(Z)}^{+\infty} z dF(z) \\ &= \mathbb{E}[Z | Z \geq V@R_\alpha(Z)]. \end{aligned} \quad (17)$$

The dual representation (Eq. 11) for $\rho(Z) = CV@R_\alpha(Z)$ holds with the set

$$\begin{aligned} \mathfrak{A} = \left\{ \zeta \in L_\infty(\Omega, \mathcal{F}, P) : \right. \\ \left. \zeta(\omega) \in [0, \alpha^{-1}] \text{ a.e. } \omega \in \Omega, \mathbb{E}[\zeta] = 1 \right\}. \end{aligned} \quad (18)$$

The conditional value-at-risk measures appear naturally in convex approximations of chance-constrained problems [7], and in a sense give a best conservative convex approximation of chance-constrained problems [8]. For a thorough discussion of coherent risk measures and extensions the interested reader is referred to Föllmer and Schied [9].

RISK AVERSE OPTIMIZATION

Consider now a generic problem of optimizing (minimizing) random objective function $F(x, \omega)$ over decision vector $x \in \mathcal{X}$. Here $\mathcal{X} \subset \mathbb{R}^n$ and $\omega \in \Omega$ with $(\Omega, \mathcal{F}, P)$ being a probability space. In a risk averse approach, the corresponding optimization problem is written in the form

$$\text{Min}_{x \in \mathcal{X}} \rho[F(x, \omega)], \quad (19)$$

where $\rho : \mathcal{Z} \rightarrow \mathbb{R}$ is an appropriate risk measure. For $x \in \mathcal{X}$, the quantity $\rho[F(x, \omega)]$ is

understood as the risk measure of the random variable $F_x : \Omega \rightarrow \mathbb{R}$, where $F_x(\omega) = F(x, \omega)$. It is assumed, of course, that for every $x \in \mathcal{X}$, the random variable F_x belongs to the space $\mathcal{Z}$ associated with the risk measure ρ .

If the risk measure ρ is coherent, then by using representation (Eq. 12) we can write Problem (19) in the following minimax form

$$\text{Min}_{x \in \mathcal{X}} \sup_{Q \in \Omega} \mathbb{E}_Q[F(x, \omega)], \quad (20)$$

where Ω is the corresponding family of probability distributions. That is, Problem (19) can be considered as a minimax stochastic programming problem with the uncertainty set Ω of probability distributions. Minimax stochastic problems of the form (Eq. 20) were also studied directly in the stochastic programming literature [10,11].

Consider, for example, the following convex combination of the expectation and $CV@R_\alpha$ risk measures

$$\rho(Z) := (1 - \gamma)\mathbb{E}[Z] + \gamma CV@R_\alpha(Z), \quad \gamma \in [0, 1].$$

In that case, by using Equation (15), Problem (19) can be written as

$$\text{Min}_{(x,t) \in \mathcal{X} \times \mathbb{R}} \mathbb{E}[H(x, t, \omega)], \quad (21)$$

where $H(x, t, \omega) := (1 - \gamma)F(x, \omega) + \gamma\alpha^{-1}[F(x, \omega) - t]_+ + \gamma t$. That is, the corresponding risk averse problem is reduced to the expected value minimization with one additional variable. Note that if $F(x, \omega)$ is (piecewise linear) convex in x , then $H(x, t, \omega)$ is (piecewise linear) convex in (x, t) . Also, the dual (minimax) representation (Eq. 20) holds with Ω being the family of probability measures Q such that

$$1 - \gamma \leq \frac{dQ}{dP} \leq 1 + \gamma(\alpha^{-1} - 1).$$

An important property of coherent risk measures is that they preserve convexity of the function $F(\cdot, \omega)$. That is, properties (A1) and (A2) of a coherent risk measure ρ imply that if $F(x, \omega)$ is convex in x for a.e. $\omega \in \Omega$, then the function $\phi(x) := \rho[F(x, \omega)]$ is also convex.

Another important property of coherent risk measures is that for them the following interchangeability principle holds [6], [12, Section 6.4.1]. Suppose that

$$F(x, \omega) := \inf_{y \in \mathcal{Y}(x, \omega)} G(x, y, \omega), \quad (22)$$

where $G: \mathbb{R}^n \times \mathbb{R}^m \times \Omega \rightarrow \mathbb{R}$ and $\mathcal{Y}: \mathbb{R}^n \times \Omega \rightrightarrows \mathbb{R}^m$ is a multifunction mapping (x, ω) into a subset of $\mathbb{R}^m$. The right-hand side of Equation (22) can be viewed as the optimal value of the second-stage problem of minimization of $G(x, y, \omega)$ subject to the feasibility constraint $y \in \mathcal{Y}(x, \omega)$. For example, in the linear case

$$\begin{aligned} G(x, y, \omega) &:= c^\top x + q(\omega)^\top y, \\ \mathcal{Y}(x, \omega) &:= \{y : T(\omega)x + W(\omega)y = h(\omega), y \geq 0\}. \end{aligned} \quad (23)$$

For coherent risk measures ρ we have that

$$\rho[F(x, \omega)] = \inf_{y(\cdot) \in \mathcal{Y}(x, \cdot)} \rho[G(x, y(\omega), \omega)], \quad (24)$$

where now $y(\cdot)$ is an element of an appropriate functional space and the notation $y(\cdot) \in \mathcal{Y}(x, \cdot)$ means that $y(\omega) \in \mathcal{Y}(x, \omega)$ for a.e. $\omega \in \Omega$. Consequently, the first-stage Problem (19) can be written as one large optimization problem:

$$\text{Min}_{x \in \mathcal{X}, y(\cdot) \in \mathcal{Y}(x, \cdot)} \rho[G(x, y(\omega), \omega)]. \quad (25)$$

In particular, suppose that the set Ω is finite, say $\Omega = \{\omega_1, \dots, \omega_K\}$. Then Problem (25) takes the form

$$\begin{aligned} &\text{Min}_{x, y_1, \dots, y_K} \rho[(G(x, y_1, \omega_1), \dots, G(x, y_K, \omega_K))] \\ &\text{subject to } x \in \mathcal{X}, y_k \in \mathcal{Y}(x, \omega_k), k = 1, \dots, K, \end{aligned} \quad (26)$$

where $y_k = y(\omega_k)$, $k = 1, \dots, K$. In the linear case (Eq. 23), Problem (26) becomes

$$\begin{aligned} &\text{Min}_{x, y_1, \dots, y_K} c^\top x + \rho[(q_1^\top y_1, \dots, q_K^\top y_K)] \\ &\text{subject to } x \in \mathcal{X}, T_k x + W_k y_k = h_k, \\ &\quad y_k \geq 0, k = 1, \dots, K. \end{aligned} \quad (27)$$

If $\rho(Z) := \mathbb{E}[Z]$ and hence $\rho[(q_1^\top y_1, \dots, q_K^\top y_K)] = \sum_{k=1}^K p_k q_k^\top y_k$, where $p_1, \dots, p_K$ are the respective probabilities, then Equation (27) becomes a large-scale formulation of a linear two-stage stochastic programming problem with recourse.

It could be emphasized that the monotonicity condition A1 is essential for the above interchangeability property and preservation of convexity of $F(\cdot, \omega)$. For instance, the risk measure defined in Equation (7) does not preserve convexity and does not allow the equivalent formulation (Eq. 27) for two-stage linear programming with recourse [13].

MULTISTAGE RISK AVERSE OPTIMIZATION

It is not completely obvious how to extend the above approach of risk measures to a multistage setting where decisions are made at several periods of time $t = 1, \dots, T$, based on information available at the time of the decision. In that respect several approaches were suggested. It is convenient to represent the evolution of the underlying data process by a scenario tree. Such a scenario tree is constructed by enumerating possible successive states (children nodes) of a current state of the system represented by its node at stage (time period) $t = 1, \dots, T-1$. A scenario is a path along this tree starting at the (unique) root node at stage $t = 1$ and ending at the last stage $t = T$.

The basic idea of multistage stochastic programming is that if we are currently at a state of the system at stage t , represented by a node of the scenario tree, then our decision at that node is based on our knowledge about the next possible realizations of the data process, which are represented by its children nodes at stage $t+1$. In the risk neutral approach one optimizes the corresponding conditional expectation of the objective function. This allows to write the associated dynamic programming equations.

This idea can be extended to a nested formulation of multistage risk averse optimization. That is, with every node at stage

$t = 1, \dots, T - 1$, is associated a risk measure defined on the space of its children nodes. Formally this can be described by the so-called *conditional risk mappings* $\rho_{t+1|\xi_{[t]}} : \mathcal{Z}_{t+1} \rightarrow \mathcal{Z}_t$, where $\xi_1, \dots, \xi_T$ is the random data process and $\xi_{[t]} := (\xi_1, \dots, \xi_t)$ is the history of the process [12,14,15]. For example, to the mean upper-semideviation risk measure (Eq. 13), corresponds the following conditional risk mapping

$$\rho_{t+1|\xi_{[t]}}(Z) := \mathbb{E}_{|t}[Z] + \lambda \left(\mathbb{E}_{|t} \left[[Z - \mathbb{E}_{|t}[Z]]_+^p \right] \right)^{1/p}, \quad (28)$$

where $\mathbb{E}_{|t}[\cdot] := \mathbb{E}[\cdot | \xi_{[t]}]$ denotes the respective conditional expectation.

The corresponding multistage risk averse optimization is formulated in accordance with the conditional structure of the constructed risk measures:

$$\begin{aligned} \text{Min } & f_1(x_1) + \rho_{2|\xi_{[1]}}[f_2(x_2, \xi_2) + \dots \\ & + \rho_{T|\xi_{[T-1]}}[f_T(x_T, \xi_T)]] \\ \text{s.t. } & x_1 \in \mathcal{X}_1, x_t \in \mathcal{X}_t(x_{t-1}, \xi_t), t = 2, \dots, T, \end{aligned} \quad (29)$$

where $f_t(x_t, \xi_t)$ are cost functions and $\mathcal{X}_t(x_{t-1}, \xi_t)$ are feasibility sets. Note that the optimization in Equation (29) is performed over feasible *policies* $x_t = x_t(\xi_{[t]})$ and the constraints should hold for almost every realization of the random process. If we set $\rho_{t+1|\xi_{[t]}}(\cdot) := \mathbb{E}[\cdot | \xi_{[t]}]$, then Equation (29) becomes a nested formulation risk neutral multistage stochastic programming problem.

The dynamic programming equations for the nested formulation (Eq. 29) can be written similar to the risk neutral case as follows

$$\begin{aligned} Q_t(x_{t-1}, \xi_{[t]}) \\ = \inf_{x_t \in \mathcal{X}_t(x_{t-1}, \xi_t)} \left\{ f_t(x_t, \xi_t) + Q_{t+1}(x_t, \xi_{[t]}) \right\}, \end{aligned} \quad (30)$$

where

$$Q_{t+1}(x_t, \xi_{[t]}) = \rho_{t+1|\xi_{[t]}}[Q_{t+1}(x_t, \xi_{[t+1]})]. \quad (31)$$

For a formal development of these ideas we refer to Refs 6 and 12, Section 6.7 of the latter.

An alternative approach is based on considering multiperiod risk measures of the form $\rho : \mathcal{Z}_1 \times \dots \times \mathcal{Z}_T \rightarrow \mathbb{R}$, where $\mathcal{Z}_t = L_p(\Omega, \mathcal{F}_t, P)$, $t = 1, \dots, T$, with $\mathcal{F}_1 \subset \dots \subset \mathcal{F}_T$ being a filtration (sequence of sigma algebras) representing information state of the system. A particular class of such multiperiod risk measures, convenient for a linear programming formulation, was suggested in Ref. 16 under the name *polyhedral risk measures*. For a further discussion of that approach we can refer to Ref. 2.

Choosing a proper risk measure is an important regulatory issue, as exemplified in governmental regulations such as Basel II accord [1] and its recent revision [2], which use Value-at-Risk (VaR) with *scenario analysis* as the risk measure for setting capital requirement for market risk. The main motivation of this article is to investigate whether VaR with scenario analysis are good risk measures for external regulation. By using the notion of *comonotonic* random variables studied in decision theory literatures such as Refs 3–8, we shall propose a new class of risk measures satisfying a new set of axioms. The new class of risk measures includes VaR with scenario analysis, in particular the current and recently revised Basel II risk measures [1,2] as special cases, and therefore provides a theoretical basis for using VaR with scenario analysis as robust risk measures for the purpose of external, regulatory risk measurement.

Broadly speaking, a risk measure attempts to assign a single numerical value to a random financial loss. Obviously, it can be problematic to use one number to summarize the whole statistical distribution of the financial loss. Therefore, one shall avoid doing this if it is at all possible. However, in many cases there is no other choice.

Examples of such cases include regulatory capital requirements, insurance risk premiums, and margin requirements in financial trading. Consequently, how to choose a good risk measure becomes a problem of great practical importance.

In this article, we only study static risk measures, that is, one period risk measures. Mathematically, let Ω be the set of all the possible states of nature at the end of an observation period, $\mathcal{X}$ be the set of financial losses under consideration, in which each financial loss is a random variable defined on Ω . Then a risk measure ρ is a mapping from $\mathcal{X}$ to the real line $\mathbb{R}$. The multiperiod or dynamic risk measures are related to dynamic consistency or time consistency for preferences [9–13].

An important property of risk measures is *robustness*. The concept of robustness has been well developed in economics and statistics. In the theory of decision or policy making in economics, the robustness of preferences or policy rules refers to the property that they can accommodate model misspecification error and would perform well across a set of alternative models. This notion of robustness has a close connection with ambiguity aversion and model uncertainty. A widely used class of robust preferences that model ambiguity and explain the famous Ellsberg Paradox [14] are the multiple priors preferences, also known as maxmin expected utility preferences, proposed by Gilboa and Schmeidler [15]. An agent with this kind of preference ranks a pay off profile Y by $\min_{P \in \mathcal{P}} \{E^P[u(Y)]\}$, where $\mathcal{P}$ is the set of subjective probabilities, or a set of priors, held by the agent, and $E^P[u(Y)]$ is the expected utility of Y under the subjective probability P . The ambiguity is reflected by the set of priors $\mathcal{P}$. Multiple priors preferences have been used to incorporate ambiguity in asset pricing [16,17]. An alternative class of robust preferences are the multiplier preferences [18–20], which also postulate that agents have multiple prior probability measures. In statistics, robustness has been studied comprehensively in the robust statistics

literature, which is mainly concerned with the distributional robustness, that is, a statistic is robust if it is insensitive to small deviation of the true underlying distribution from the assumed distribution [21,22]. Loosely speaking, a robust statistic is insensitive to small changes in the data, which are either small changes in all the observations or large changes in a few observations (outliers).

A risk measure is said to be robust if (i) it can accommodate model misspecification (possibly by incorporating multiple priors); and (ii) it is insensitive to small changes in the data (by using robust statistics).

Another important issue related to risk measures, which has not been well addressed in the existing literature, is the objective of a risk measure. In terms of objectives, risk measures can be classified into two categories: *internal* risk measures used for internal risk management at individual institutions, and *external* risk measures used for external regulation and imposed for all the relevant institutions. Internal risk measures are proposed for the interests of institutions' shareholders or managers, while external risk measures are used by regulatory agencies to maintain safety and soundness of the financial system. One risk measure may be suitable for internal management, but not for external regulation, and vice versa. There is no reason to believe that one unique risk measure can fit all needs. For example, variance is an internal risk measure that is commonly used for hedging and asset allocation in institutions. However, variance is not a good risk measure for calculating capital requirements in external regulation, because it does not help to achieve the regulators' objective of ensuring that with very high confidence level, for example, 99.9% institutions have enough capital to absorb their losses. In contrast, VaR, which summarizes the worst loss of a portfolio at a given confidence level, better suits the needs of regulators and, therefore, is more suitable for external regulation than variance.

Another reason for the existence of internal and external risk measures lies in the fact that the information available for institutions and regulators are different.

Institutions have more information and hence could tailor their risk measures to incorporate all of it. External regulators have access to a subset of information only. Therefore, their way of measuring risk is different. No amount of disclosure requirements can eliminate private information that institutions have.

In this article, we shall focus on external risk measures from the viewpoint of regulatory agencies. We will show in the sections titled "Legal Motivation" and "The Main Reason to Relax Subadditivity: Robustness" that an external risk measure should be robust but *coherent risk measures* are generally not robust. We will then propose a new class of risk measures that includes a subclass of robust ones in the section titled "Main Results: Natural Risk Statistics."

VaR WITH SCENARIO ANALYSIS AND RISK STATISTICS

Value-at-Risk

One of the most widely used risk measures in financial regulation and risk management is VaR, which is a quantile at some predefined probability level. More precisely, let $F(\cdot)$ be the distribution function of X , then for given $\alpha \in (0, 1)$, VaR of the loss variable X at level α is defined as the α -quantile of X , that is,

$$\text{VaR}_\alpha(X) := \inf\{x \mid F(x) \geq \alpha\} = F^{-1}(\alpha). \quad (1)$$

In practice, VaR is usually estimated from samples of the random loss X , that is, a data set $\tilde{x} = (x_1, \dots, x_n) \in \mathbb{R}^n$. Let $(x_{(1)}, \dots, x_{(n)})$ be the sample order statistics and $F_n(x) := \frac{1}{n} \sum_{i=1}^n 1_{\{x_i \leq x\}}$ be the empirical distribution function. The most commonly used estimator for $\text{VaR}_\alpha(X)$ is the sample quantile $x_{([\alpha n])} = F_n^{-1}(\alpha)$, where $[\alpha n]$ is the smallest integer that is no less than αn . The sample quantile is strongly consistent and asymptotically normal [23]. See Refs 24 and 25 for more comprehensive discussion of VaR.

VaR with Scenario Analysis and Basel II Risk Measures

VaR with scenario analysis is the class of risk measures that involve the calculation and

comparison of VaR under different scenarios. A simple example of VaR with scenario analysis is

$$\max\{\text{VaR}_1, \text{VaR}_2\}, \quad (2)$$

where VaR_i is the value of VaR calculated under scenario i , $i = 1, 2$.

Basel II Accord [1] uses VaR with scenario analysis to calculate capital requirement for market risk. More precisely, Basel II Accord specifies that the market risk capital requirement at any particular day t for banks using the internal models approach is calculated as

$$c_t = \max \left\{ \text{VaR}_{t-1}, k \cdot \frac{1}{60} \sum_{i=1}^{60} \text{VaR}_{t-i} \right\}, \quad (3)$$

where k is a constant that is no less than 3; VaR_{t-i} is the 10-day VaR at 99% confidence level calculated on day $t-i$, $i = 1, \dots, 60$. VaR_{t-i} is usually estimated from a data set $\tilde{x}^i = (x_1^i, x_2^i, \dots, x_{n_i}^i) \in \mathbb{R}^{n_i}$, which are based on the most recent one year observation of market variables up to day $t-i$ and can be generated by historical simulation or Monte Carlo simulation [24,25]. Hence, VaR_{t-i} corresponds to the scenario based on the information available on the day $t-i$. Therefore, the risk measure defined in Equation (3) is a VaR with scenario analysis that involves 60 scenarios.

During the financial crisis that started in late 2007, it was found that most banks' actual losses were significantly higher than the capital requirement calculated by Equation (3) [2]. In addition, the risk measure (Eq. 3) has been criticized for its procyclicality [26]. Therefore, the Basel committee recently revised the Basel II market risk framework [2]. The revised market risk capital requirement is defined as

$$c_t = \max \left\{ \text{VaR}_{t-1}, k \cdot \frac{1}{60} \sum_{i=1}^{60} \text{VaR}_{t-i} \right\} + \max \left\{ \text{sVaR}_{t-1}, \ell \cdot \frac{1}{60} \sum_{i=1}^{60} \text{sVaR}_{t-i} \right\}, \quad (4)$$

where VaR_{t-i} is defined the same as in Equation (3); k and ℓ are constants no less than 3; sVaR_{t-i} is called the *stressed* VaR on day $t-i$, which is calculated under the scenario that the financial market is under significant stress such as the one that happened during the period from 2007 to 2008. The additional capital requirement based on stressed VaR helps to reduce the procyclicality of the original risk measure (Eq. 3).

Interestingly, the risk measures defined in Equations (2), (3), and (4) do not belong to any existing theoretical framework of risk measures in the literature. In this article, we are going to define a new class of risk measures that include these risk measures as special cases and thus provide theoretical basis for the use of VaR with scenario analysis in external regulation.

Risk Statistics: Data-based Risk Measures

In external regulation, the random loss X under consideration corresponds to the loss of the whole trading book of a financial institution, which contains all kinds of assets across many sectors. Specifying accurate models for X (under different scenarios) involves modeling the joint distribution of a large number of correlated risk factors and is hence usually very difficult. Therefore, the behavior of X under different scenarios is usually represented by different sets of data observed or generated under different scenarios, and the risk measurement of the loss is directly estimated from the data.

More precisely, suppose the behavior of the random loss X is represented by a collection of data $\tilde{x} = (\tilde{x}^1, \tilde{x}^2, \dots, \tilde{x}^m) \in \mathbb{R}^n$, where $\tilde{x}^i = (x_1^i, \dots, x_{n_i}^i) \in \mathbb{R}^{n_i}$ is the data subset that corresponds to the i -th scenario; n_i is the sample size of $\tilde{x}^i$; $n_1 + n_2 + \dots + n_m = n$; for each $i = 1, \dots, m$, $\tilde{x}^i$ can be a data set based on historical observations, or a data set simulated according to a well-defined procedure or model, or a mixture of historical and simulated data. The random loss X can be discrete or continuous. For example, the data used in the calculation of the revised Basel II risk measure defined in Equation (4) comprise 120 data subsets that correspond to 120 different scenarios.

A *risk statistic* $\hat{\rho}$ is simply a mapping from $\mathbb{R}^n$ to $\mathbb{R}$. It is a data-based risk measure that maps $\tilde{x}$, the data representation of the random loss X , to $\hat{\rho}(\tilde{x})$, the risk measurement of X .

In this article, we will define a new set of axioms for risk statistics instead of risk measures, because risk statistics directly measure risk from data without specifying subjective models, which greatly reduces model misspecification error.

REVIEW OF EXISTING RISK MEASURES

There are mainly two families of static risk measures suggested in the literature, coherent and convex risk measures, and insurance risk measures. Both are based on axiomatic approaches, by which some axioms are postulated first, and then all the risk measures satisfying the axioms are identified.

Coherent and Convex Risk Measures

Axioms. Coherent risk measures [27] satisfy the following axioms:

Axiom A1. Translation invariance: $\rho(X + b) = \rho(X) + b$, $\forall b \in \mathbb{R}, \forall X \in \mathcal{X}$.

Axiom A2. Positive homogeneity: $\rho(aX) = a\rho(X)$, $\forall a \geq 0, \forall X \in \mathcal{X}$.

Axiom A3. Monotonicity: $\rho(X) \leq \rho(Y)$, if $X \leq Y$.

Axiom A4. Subadditivity: $\rho(X + Y) \leq \rho(X) + \rho(Y)$, $\forall X, Y \in \mathcal{X}$.

What is questionable lies in the subadditivity requirement in Axiom A4, which basically means that “a merger does not create extra risk” [27, p. 209]. We will discuss the controversies related to this axiom in the section titled “Other Reasons to Relax Subadditivity.”

It is shown in Refs 22, 27, and 28 that a risk measure ρ is coherent if and only if there exists a family $\mathcal{Q}$ of probability measures, such that $\rho(X) = \sup_{Q \in \mathcal{Q}} \{E^Q[X]\}$, $\forall X \in \mathcal{X}$, where $E^Q[X]$ is the expectation of X under the probability measure Q . Therefore, measuring risk by a coherent risk measure amounts to computing maximal expectation

under a set of prior probability measures. An equivalent approach of defining coherent risk measures via acceptance sets is also presented in Refs 27 and 28.

A special case of coherent risk measures is the *tail conditional expectation* (TCE) [27, 29–31]. More precisely, for a loss X with a continuous distribution, TCE at level α of X is defined by

$$\text{TCE}_\alpha(X) := E[X | X \geq \text{VaR}_\alpha(X)]. \quad (5)$$

For X with general distributions, $\text{TCE}_\alpha(X)$ is defined as a regularized version of $E[X | X \geq \text{VaR}_\alpha(X)]$ [32].

Another property of risk measures is called *law invariance*, as stated in the following Axiom A5.

Axiom A5. Law invariance: $\rho(X) = \rho(Y)$, if X and Y have the same distribution.

A risk measure is called a *law-invariant coherent risk measure*, if it satisfies Axiom A1–A5. Kusuoka [33] gives a representation for the law-invariant coherent risk measures.

Convex risk measures proposed in Refs 34 and 35 are risk measures that satisfy Axiom A1, A3, and the following convexity axiom A6, which relaxes the positive homogeneity and subadditivity axioms in coherent risk measures.

Axiom A6. Convexity: $\rho(\lambda X + (1 - \lambda)Y) \leq \lambda\rho(X) + (1 - \lambda)\rho(Y)$, $\forall X, Y \in \mathcal{X}, \forall \lambda \in [0, 1]$.

Main Drawbacks of Coherent and Convex Risk Measures. A main drawback of coherent risk measures is that in general, they are not robust (see the section titled “Comparison with Coherent Risk Measures”). For example, TCE is too sensitive to the modeling assumption for the tails of loss distributions, and it is sensitive to outliers in the data (see the section titled “Tail Conditional Median: A Robust Risk Measure”). However, robustness is an indispensable requirement for external risk measures, as we will point out in the section titled “The Main Reason to Relax Subadditivity: Robustness.” Hence, coherent

risk measures are not suitable for external regulation.

Another drawback of coherent and convex risk measures is that they rule out VaR, which does not satisfy subadditivity or convexity universally [27]. This posts a serious inconsistency between the academic theory and governmental practice. The inconsistency is due to the subadditivity Axiom A4. By relaxing this axiom and requiring subadditivity only for comonotonic random variables, we are able to define a new class of risk measures that include VaR and more generally, VaR with scenario analysis, thus eliminating the inconsistency.

Insurance Risk Measures

Insurance risk measures [8] satisfy the following axioms:

Axiom B1. Law invariance: the same as Axiom A5.

Axiom B2. Monotonicity: $\rho(X) \leq \rho(Y)$, if $X \leq Y$.

Axiom B3. Comonotonic additivity: $\rho(X + Y) = \rho(X) + \rho(Y)$, if X and Y are comonotonic. (X and Y are *comonotonic* if $(X(\omega_1) - X(\omega_2))(Y(\omega_1) - Y(\omega_2)) \geq 0$ holds almost surely for ω_1 and ω_2 in Ω .)

Axiom B4. Continuity: $\lim_{d \rightarrow 0} \rho((X - d)^+) = \rho(X^+)$, $\lim_{d \rightarrow \infty} \rho(\min(X, d)) = \rho(X)$, and $\lim_{d \rightarrow -\infty} \rho(\max(X, d)) = \rho(X)$, $\forall X$. ($x^+ := \max(x, 0)$, $\forall x \in \mathbb{R}$).

Axiom B5. Scale normalization: $\rho(1) = 1$.

The notion of comonotonic random variables is studied in Refs 3, 5, and 36. The psychological motivation of comonotonic random variables comes from alternative models to expected utility theory including the prospect theory (see the section titled “Theory of Choice under Uncertainty and Risk”). Dhaene *et al.* [37] give a recent review of risk measures and comonotonicity.

VaR with scenario analysis, such as the Basel II risk measures (Eqs 3 and 4), are not insurance risk measures, although VaR itself is an insurance risk measure (see Ref. 36 for the proof that VaR satisfies Axiom B3). An insurance risk measure does not necessarily satisfy subadditivity.

A main drawback of insurance risk measures is that neither can they incorporate multiple priors of the probability distributions on the set of scenarios, nor can they incorporate multiple approaches to measure risk under each scenario (see the section titled “Comparison with Insurance Risk Measures” for more detailed discussion).

The main reason that insurance risk measures cannot incorporate multiple priors is that they require comonotonic additivity. To incorporate multiple priors, we shall relax the comonotonic additivity to comonotonic subadditivity in the section titled “Main Results: Natural Risk Statistics.”

The mathematical concept of comonotonic subadditivity is also studied independently in Refs 38 and 39, which give representations of the functionals satisfying comonotonic subadditivity or comonotonic convexity from a mathematical perspective. There are several differences between Refs 38 and 39 and this article. See Ref. 40 for the details.

LEGAL MOTIVATION

In this section, we shall discuss two basic concepts of law, that is, legal realism and legal positivism, which motivate us to argue that: (i) External risk measures should be robust, because robustness is essential for law enforcement; (ii) External risk measures should have consistency with people’s behavior, because law should reflect society norms.

Legal Realism and Robustness of Law

Legal realism is the viewpoint that the legal decision of a court regarding a case is determined by the actual practices of judges, rather than the law set forth in statutes and precedents. All the legal rules contained in statutes and precedents have uncertainty due to the uncertainty in human language and that human beings are unable to anticipate all the possible future circumstances [41, p. 128]. Hence, a law is only a guideline for judges and enforcement officers [41, pp. 204–205], that is, a law is only intended to be the average of what judges and officers will decide. This concerns the robustness of law, that is, a law should be established in

such a way that different judges will reach similar conclusions when they implement the law.

In particular, external risk measures imposed in banking regulation should be robust with respect to underlying models and data. However, coherent risk measures generally lack robustness, as manifested in Theorem 3.

Legal Positivism and Social Norm

Legal positivism is the thesis that the existence and content of law depend on social norms and not on their merits. It is based on the argument that if a system of rules are to be imposed by force in the form of law, there must be a sufficient number of people who accept it voluntarily; without their voluntary cooperation, the coercive power of law and government cannot be established [41, pp. 201–204].

Therefore, external risk measures imposed in banking regulations should also reflect most people's behavior. However, decision theory suggests that most people's decision can violate the subadditivity Axiom A4 (see the section titled "Theory of Choice under Uncertainty and Risk" for details).

THE MAIN REASON TO RELAX SUBADDITIVITY: ROBUSTNESS

Robustness is Indispensable for External Risk Measures

In determining capital requirement, regulators impose a risk measure and allow institutions to use their own internal risk models and private data in the calculation. For example, Basel II's internal models approach allows institutions to use their own internal models to calculate the capital requirement for market risk.

There are two issues rising from the use of internal models and private data in external regulation: (i) the data can be noisy, flawed, or unreliable; (ii) there can be several statistically indistinguishable models for the same asset or portfolio due to limited amount of available data.

For example, the heaviness of tail distributions cannot be identified in many

cases. Although it is accepted that stock returns have tails heavier than those of normal distributions, one school of thought believes that the tails are exponential-type, while another believes that the tails are power-type. Heyde and Kou [42] show that it is very difficult to distinguish between exponential-type and power-type tails with 5,000 observations (about 20 years of daily observations). This is mainly because the quantiles of exponential-type distributions and power-type distributions may overlap. Hence, the tail behavior may be a subjective issue depending on people's modeling preferences.

To address the two issues above, external risk measures should demonstrate robustness with respect to model misspecification and small changes in the data. From a regulator's viewpoint, an external risk measure must be unambiguous, stable, and be implemented consistently across all the relevant institutions, no matter what internal beliefs or internal models each individual institution may have. In situations when the correct model cannot be identified, two institutions that have exactly the same portfolio can use different internal models, both of which can obtain the approval of the regulator. From the regulator's viewpoint, the same portfolio should incur the same or almost the same amount of regulatory capital. Therefore, the external risk measure should be robust, otherwise different institutions can be required to hold very different regulatory capital for the same risk exposure, which makes the risk measure unacceptable to most institutions.

In addition, if the external risk measure is not robust, institutions can take regulatory arbitrage by choosing a model that significantly reduces the capital requirement or by manipulating the input data.

Coherent Risk Measures are not Robust

The robustness of coherent risk measures is questionable in two aspects.

First, the theory of coherent risk measures suggests to use TCE to measure risk. However, as we will show in the section titled "Tail Conditional Median: A Robust Risk Measure," TCE is sensitive to modeling

assumptions of heaviness of tail distribution and to outliers in the data.

Second, in general, coherent risk measures are not robust. We will prove in Theorem 3 that every empirically law-invariant coherent risk measure puts larger weights on larger observations, and hence is obviously sensitive to small changes in the data.

Tail Conditional Median: A Robust Risk Measure

We propose a more robust risk measure, tail conditional median (TCM), which is a special case of the new class of risk measures to be defined in the section titled “Main Results: Natural Risk Statistics.” TCM of loss X at level α is defined as

$$\text{TCM}_\alpha(X) = \text{VaR}_{\frac{1+\alpha}{2}}(X).$$

It is called conditional median, because for X with a continuous distribution,

$$\begin{aligned} \text{TCM}_\alpha(X) &= \text{VaR}_{\frac{1+\alpha}{2}}(X) \\ &= \text{median}[X|X \geq \text{VaR}_\alpha(X)], \quad (6) \end{aligned}$$

that is, the conditional median of X given that $X \geq \text{VaR}_\alpha(X)$. For X with a general distribution involving discontinuity, $\text{VaR}_{\frac{1+\alpha}{2}}(X)$ can be viewed as a regularized version of $\text{median}[X|X \geq \text{VaR}_\alpha(X)]$.

The equality (Eq. 6) shows that if one wants to measure the size of loss beyond the confidence level α , one can use VaR at a higher level $\frac{1+\alpha}{2}$, which gives the conditional median of the size of loss beyond level α . This contradicts the criticism on VaR that VaR cannot provide information about the size of loss beyond certain confidence level.

There are many examples in the existing literature showing that VaR violates subadditivity, for example, the examples on p. 216 and p. 217 of Ref. 27. However, it is straightforward to verify that in those examples subadditivity will not be violated if one replaces VaR_α by TCM_α .

TCM can be shown to be more robust than TCE by at least four standard tools in robust statistics [21,22]: (i) influence functions, (ii)

asymptotic breakdown points, (iii) continuity of statistical functional, and (iv) finite sample breakdown points. For example, TCE has an unbounded influence function but TCM has a bounded influence function, which implies that TCM is more robust than TCE with respect to outliers in the data. See Ref. 40 for more detailed discussion.

TCE is highly model-dependent, in particular, sensitive to modeling assumption of extreme tails of loss distribution, as illustrated in Fig. 1. The left panel of the figure shows the value of TCE_α with respect to $\log(1-\alpha)$ for Laplace and T distributions with degree of freedom 3, 5, and 12, which are normalized to have mean 0 and variance 1, where α is in the range [95%, 99.9%]. The right panel of the figure shows the value of TCM_α for those distributions. Apparently, the range of variation of TCM_α with respect to change of modeling assumption is much smaller than that of TCE_α . For example, with $\alpha = 99.6\%$, the variation of TCE_α is 1.44, whereas the variation of TCM_α is only 0.75. In the context of capital requirement, suppose a bank's trading portfolio loss is σX , where $\sigma = \$1$ billion and X has mean 0 and variance 1, which can be modeled to have one of the four distributions. At confidence level $\alpha = 99\%$, if TCE_α is used to calculate capital requirement, the capital requirement for banks using one of the four models will be in the range of [2.95, 4.05] billion; in contrast, if TCM_α is used, the range will be [2.79, 3.38] billion. Hence, TCM results in much more comparable capital requirements across banks when they may use different models.

It is worth noticing that TCE is not necessarily larger than TCM. Eling and Tibiletti [43] compare TCE and TCM for a set of capital market data and find that although TCE is on average about 10% higher than TCM at standard confidence levels, TCM is higher than TCE in about 10% of the studied cases.

Robust Risk Measures Versus Conservative Risk Measures

A risk measure is said to be more conservative than another, if it generates higher risk measurement than the other for the

Figure 1. The left panel shows TCE for Laplacian distribution and T distributions with degree of freedom 3, 5, 12, which are normalized to have mean 0 and variance 1. The right panel shows TCM for the same set of distributions. The x-axis is $\log(1 - \alpha)$ where $\alpha \in [0.95, 0.999]$. TCM is less sensitive to modeling assumption of the underlying distribution than TCE, as the change of its value with respect to change of underlying distributions has a narrower range.

same underlying risk exposure. The use of more conservative risk measures in external regulation is desirable from a regulator's viewpoint, since it generally increases the safety of the financial system (Of course, risk measures should not be too conservative to retard the economic growth).

There is no contradiction between the robustness and the conservativeness of external risk measures. Robustness addresses the issue of whether a risk measure can be implemented consistently, so it is a requisite property of an external risk measure. Conservativeness addresses the issue of how stringently an external risk measure should be implemented, given that it can be implemented consistently. In other words, being more conservative is a further desirable property of an external risk measure. An external risk measure should be robust in the first place before one can consider the

issue of how to implement it in a conservative way.

By the following approaches, one can construct an external risk measure that is both robust and conservative:

1. More scenarios can be included to incorporate the possible effects of extreme events that lie outside normal market conditions. For example, the revised Basel II risk measure Equation (4) takes into account 60 more stressed scenarios compared to the Basel II risk measure Equation (3).
2. Regulators can simply multiply the original risk measure by a larger constant to obtain a more conservative risk measure. For example, one can use larger k in Equation (3). This is equivalent to choosing a larger s in Axiom C1 for the new risk measures (see the

section titled “Main Results: Natural Risk Statistics”).

3. One can use more weights or more prior probability measures to define the external risk measure. See the section titled “Main Results: Natural Risk Statistics” for more detailed discussion.

OTHER REASONS TO RELAX SUBADDITIVITY

Diversification and Tail Subadditivity of VaR

The subadditivity axiom for coherent risk measures and the convexity axiom for convex risk measures conform to the idea that diversification does not increase risk. There are two main motivations for diversification. One is based on the simple observation that $SD(X + Y) \leq SD(X) + SD(Y)$, for any two random variables X and Y with finite second moments, where $SD(\cdot)$ denotes standard deviation. The other is based on expected utility theory. Samuelson [44] shows that any investor with a strictly concave utility function will uniformly diversify among independently and identically distributed risks with finite second moments (see Refs 45–48 for the discussion on whether diversification is beneficial when the asset returns are dependent). Both of the two motivations require finiteness of second moments of the risks.

Is diversification still preferable for risks with infinite second moments? The answer can be no. Ibragimov and Walden [49] show that diversification is not preferable for unbounded extremely heavy-tailed distributions, in the sense that the expected utility of the diversified portfolio is smaller than that of the undiversified portfolio. They also show that, investors with certain S-shaped utility functions would prefer nondiversification, even for bounded risks. An S-shaped utility function is convex in the domain of losses, which is supported by experimental results and prospect theory [6,50]. See the section titled “Theory of Choice under Uncertainty and Risk” for more discussion on prospect theory.

VaR has been criticized because it does not satisfy subadditivity universally, but this

criticism is unreasonable because even diversification is not universally preferable. In fact, Danielsson *et al.* [51] show that VaR is subadditive in the tail region, provided that the tail of the joint distribution is not extremely fat (with tail index less than one). The simulations that they carry out also show that VaR_α is indeed subadditive when $\alpha \in [95\%, 99\%]$ for most practical applications.

To summarize, there is no conflict between the use of VaR and diversification. When the risks do not have extremely heavy tails, diversification is preferred and VaR satisfies subadditivity in the tail region; when the risks have extremely heavy tails, diversification may not be preferable and VaR may fail to satisfy subadditivity.

Asset returns with tail index less than one have very fat tails. They are hard to find and easy to identify. Danielsson *et al.* [51] argue that they can be treated as special cases in financial modeling. Even if one encounters an extremely fat tail and insists on tail subadditivity, Garcia *et al.* [52] show that when tail thickness causes violation of subadditivity, a decentralized risk management team may restore the subadditivity for VaR by using proper conditional information.

Does A Merger Always Reduce Risk

Subadditivity basically means that “a merger does not create extra risk” [27, p. 209]. However, Dhaene *et al.* [53] point out that a merger may increase risk, particularly due to bankruptcy protection for institutions. For example, it is better to split a risky trading business into a separate subsidiary institution. This way, even if the loss from the subsidiary institution is enormous, the parent institution can simply let the subsidiary institution go bankrupt, thus confining the loss to that one subsidiary institution. Therefore, creating subsidiary institutions may incur less risk and a merger may increase risk.

For example, the collapse of Britain’s Barings Bank in February 1995, due to the failure of a single trader (Nick Leeson) in Singapore clearly indicates that a merger may increase risk. Had Barings Bank setup a separate institution for its Singapore unit, the bankruptcy in that unit would not have sunk the entire bank.

Theory of Choice under Uncertainty and Risk

Risk measures have a close connection with the psychological and economic theory of people's choices under uncertainty and risk. Tversky and Kahneman [6,50] point out that people's choices under risky prospects are inconsistent with the basic tenets of expected utility theory and propose an alternative model, called *prospect theory*, which can explain a variety of preference anomalies. The axiomatic analysis of prospect theory is presented in Refs 6 and 7. Many other people have studied alternative models to expected utility theory, such as Refs 3–5, 54.

Kou *et al.* [40] provide a simple example showing that risks associated with noncomonotonic random variables can violate subadditivity, because people are risk seeking instead of risk averse in choices between probable and sure losses, as implied by prospect theory. The example also shows that most people's behavior can violate the subadditivity axiom.

Schmeidler [4] points out that risk preferences for comonotonic random variables are easier to justify than those for arbitrary random variables and accordingly relaxes the independence axiom in expected utility theory to the comonotonic independence axiom that applies only to comonotonic random variables. Tversky and Kahneman [6] and Wakker and Tversky [7] also find that prospect theory is characterized by the axioms that impose conditions only on comonotonic random variables and are thus less restrictive than their counterparts in expected utility theory.

Motivated by the prospect theory, we think it may be appropriate to relax the subadditivity to comonotonic subadditivity. In other words, we impose $\rho(X + Y) \leq \rho(X) + \rho(Y)$ only for comonotonic random variables X and Y when defining the new risk measures in the section titled “Main Results: Natural Risk Statistics.”

MAIN RESULTS: NATURAL RISK STATISTICS

In this section, we will define and fully characterize the new data-based risk measures, which we call the natural risk statistics.

As discussed in the section titled “Risk Statistics: Data-Based Risk Measures,” we are going to measure the risk from a collection of data $\tilde{x} = (\tilde{x}^1, \tilde{x}^2, \dots, \tilde{x}^m) \in \mathbb{R}^n$ that represents the behavior of the random loss X , where $\tilde{x}^i = (x_1^i, x_2^i, \dots, x_{n_i}^i)$ is the data subset that corresponds to scenario i . The risk measurement will be given by $\hat{\rho}(\tilde{x})$, where $\hat{\rho} : \mathbb{R}^n \rightarrow \mathbb{R}$ is a risk statistic.

Axioms and Representations for Natural Risk Statistics

At first, we define the concept of scenario-wise comonotonicity for two data sets.

Definition 1. Two data sets $\tilde{x} = (\tilde{x}^1, \tilde{x}^2, \dots, \tilde{x}^m) \in \mathbb{R}^n$ and $\tilde{y} = (\tilde{y}^1, \tilde{y}^2, \dots, \tilde{y}^m) \in \mathbb{R}^n$ are scenario-wise comonotonic, if for $\forall i$, $\forall 1 \leq j, k \leq n_i$, $(x_j^i - x_k^i)(y_j^i - y_k^i) \geq 0$.

Then we postulate the following axioms for a risk statistic $\hat{\rho}$.

Axiom C1. Positive homogeneity and translation scaling: $\hat{\rho}(a\tilde{x} + b\mathbf{1}) = a\hat{\rho}(\tilde{x}) + s \cdot b$, $\forall \tilde{x} \in \mathbb{R}^n$, $\forall a \geq 0$, $\forall b \in \mathbb{R}$, where $s > 0$ is a constant, $\mathbf{1} = (1, 1, \dots, 1) \in \mathbb{R}^n$.

Axiom C2. Monotonicity: $\hat{\rho}(\tilde{x}) \leq \hat{\rho}(\tilde{y})$ for any $\tilde{x} \leq \tilde{y}$, where $\tilde{x} \leq \tilde{y}$ means $x_j^i \leq y_j^i$, $\forall j, i$.

The two axioms above (with $s = 1$) have been proposed for coherent risk measures.

Axiom C3. Scenario-wise comonotonic subadditivity: $\hat{\rho}(\tilde{x} + \tilde{y}) \leq \hat{\rho}(\tilde{x}) + \hat{\rho}(\tilde{y})$, for any $\tilde{x}$ and $\tilde{y}$ that are scenario-wise comonotonic.

In Axiom C3, we relax the subadditivity requirement in coherent risk measures so that the subadditivity is only required for comonotonic random variables. This also relaxes the comonotonic additivity requirement in insurance risk measures.

Axiom C4. Scenario-wise permutation invariance:

$$\hat{\rho}((\tilde{x}^1, \tilde{x}^2, \dots, \tilde{x}^m)) = \hat{\rho}((x_{p_1,1}^1, \dots, x_{p_1,n_1}^1, x_{p_2,1}^2, \dots, x_{p_2,n_2}^2, \dots, x_{p_m,1}^m, \dots, x_{p_m,n_m}^m)),$$

for any permutation $(p_{i,1}, \dots, p_{i,n_i})$ of $(1, 2, \dots, n_i)$, $i = 1, \dots, m$.

This axiom can be considered as the counterpart of the law invariance Axiom A5 in the empirical setting. It means that if two data set $\tilde{x}$ and $\tilde{y}$ have the same empirical distribution under each scenario, then $\tilde{x}$ and $\tilde{y}$ should give the same measurement of risk.

Definition 2. A risk statistic $\hat{\rho} : \mathbb{R}^n \rightarrow \mathbb{R}$ is called a natural risk statistic if it satisfies Axiom C1–C4.

The following representation theorem fully characterizes the natural risk statistics.

Theorem 1. (i) For a given constant $s > 0$ and an arbitrarily given set of weights $\mathcal{W} = \{\tilde{w}\} \subset \mathbb{R}^n$ with each $\tilde{w} = (w_1^1, \dots, w_{n_1}^1, \dots, w_1^m, \dots, w_{n_m}^m) \in \mathcal{W}$ satisfying the following conditions:

$$\sum_{j=1}^{n_1} w_j^1 + \sum_{j=1}^{n_2} w_j^2 + \dots + \sum_{j=1}^{n_m} w_j^m = 1, \quad (7)$$

$$w_j^i \geq 0, j = 1, \dots, n_i; i = 1, \dots, m, \quad (8)$$

define a risk statistic $\hat{\rho} : \mathbb{R}^n \rightarrow \mathbb{R}$ as follows:

$$\begin{aligned} \hat{\rho}(\tilde{x}) := s \cdot \sup_{\tilde{w} \in \mathcal{W}} & \left\{ \sum_{j=1}^{n_1} w_j^1 x_{(j)}^1 + \sum_{j=1}^{n_2} w_j^2 x_{(j)}^2 + \dots \right. \\ & \left. + \sum_{j=1}^{n_m} w_j^m x_{(j)}^m \right\}, \\ \forall \tilde{x} = (\tilde{x}^1, \tilde{x}^2, \dots, \tilde{x}^m) & \in \mathbb{R}^n, \quad (9) \end{aligned}$$

where $(x_{(1)}^i, \dots, x_{(n_i)}^i)$ is the order statistics of $\tilde{x}^i = (x_1^i, \dots, x_{n_i}^i)$ with $x_{(n_i)}^i$ being the largest, $i = 1, \dots, m$. Then the risk statistic defined in Equation (9) is a natural risk statistic.

(ii) If $\hat{\rho}$ is a natural risk statistic, then there exists a set of weights $\mathcal{W} = \{\tilde{w} = (\tilde{w}^1, \tilde{w}^2, \dots, \tilde{w}^m)\} \subset \mathbb{R}^n$ with each $\tilde{w} \in \mathcal{W}$

satisfying condition (7) and (8), such that

$$\begin{aligned} \hat{\rho}(\tilde{x}) = s \cdot \sup_{\tilde{w} \in \mathcal{W}} & \left\{ \sum_{j=1}^{n_1} w_j^1 x_{(j)}^1 + \sum_{j=1}^{n_2} w_j^2 x_{(j)}^2 + \dots \right. \\ & \left. + \sum_{j=1}^{n_m} w_j^m x_{(j)}^m \right\}, \\ \forall \tilde{x} = (\tilde{x}^1, \tilde{x}^2, \dots, \tilde{x}^m) & \in \mathbb{R}^n. \end{aligned} \quad (10)$$

Proof. See Ref. 40 (for the case of $m = 1$, see also Ref. 55). Q.E.D.

The natural risk statistics can also be characterized via acceptance sets as in the case of coherent risk measures. See Ref. 40 for the details.

The Basel II risk measures, and other VaR with scenario analysis, are special cases of natural risk statistics. More precisely, we have the following theorem:

Theorem 2. The Basel II risk measure defined in Equation (3) and the revised Basel II risk measure defined in Equation (4) are both natural risk statistics.

Proof. See Ref. 40. Q.E.D.

Robust Natural Risk Statistics

Natural risk statistics include a subclass of risk statistics that are robust in two aspects: (i) they can accommodate model misspecification by incorporating multiple prior probability measures on the set of scenarios; (ii) they are insensitive to small changes in the data by using robust statistics for each scenario.

Let $\hat{\rho}$ be a natural risk statistic defined in Equation (9) that corresponds to the set of weights $\mathcal{W}$. Define a map $\phi : \mathcal{W} \rightarrow \mathbb{R}^m \times \mathbb{R}^n$ such that for each $\tilde{w} \in \mathcal{W}$, $\phi(\tilde{w}) := (\tilde{p}, \tilde{q})$, where $\tilde{p} := (p^1, \dots, p^m)$, $p^i := \sum_{j=1}^{n_i} w_j^i$,

and $\tilde{q} := (q_1^1, \dots, q_{n_1}^1, \dots, q_1^m, \dots, q_{n_m}^m)$, $q_j^i := 1_{\{p_i > 0\}} w_j^i / p_i$. Then $\hat{\rho}$ can be written as

$$\hat{\rho}(\tilde{x}) = s \cdot \sup_{(\tilde{p}, \tilde{q}) \in \phi(\mathcal{W})} \left\{ \sum_{i=1}^m p^i \hat{\rho}^i(\tilde{x}^i) \right\}, \text{ where}$$

$$\hat{\rho}^i(\tilde{x}^i) := \sum_{j=1}^{n_i} q_j^i x_{(j)}^i. \quad (11)$$

Thus, each weight $\tilde{w} \in \mathcal{W}$ specifies: (i) the prior probability measure $\tilde{p}$ on the set of scenarios; and (ii) the subsidiary risk statistic $\hat{\rho}^i$ for each scenario i , which measures risk from data subset $\tilde{x}^i$.

Hence, $\hat{\rho}$ can be robust to model misspecification by incorporating multiple prior probability measures on the set of scenarios. And $\hat{\rho}$ can be robust to small changes in the data if each subsidiary risk statistic $\hat{\rho}^i(\tilde{x}^i)$ is a robust statistic, for example, VaR, or other robust L-statistics [22, Chapter 3].

The Basel II risk measures defined in Equations (3) and (4) incorporate multiple priors of probability distributions on the set of scenarios and use VaR as subsidiary risk statistics. Hence, they are robust natural risk statistics.

COMPARISON WITH COHERENT AND INSURANCE RISK MEASURES

Comparison with Coherent Risk Measures

To compare with coherent risk measures, we first define the law-invariant coherent risk statistics, the data-based versions of law-invariant coherent risk measures.

Definition 3. A risk statistic $\hat{\rho} : \mathbb{R}^n \rightarrow \mathbb{R}$ is called a law-invariant coherent risk statistic, if it satisfies Axiom C1, C2, C4, and the following axiom E3.

Axiom E3. Subadditivity: $\hat{\rho}(\tilde{x} + \tilde{y}) \leq \hat{\rho}(\tilde{x}) + \hat{\rho}(\tilde{y})$, $\forall \tilde{x}, \tilde{y} \in \mathbb{R}^n$.

We have the following representation theorem for law-invariant coherent risk statistics.

Theorem 3. (i) For a given constant $s > 0$ and an arbitrarily given set of weights $\mathcal{W} = \{\tilde{w}\} \subset \mathbb{R}^n$ with each $\tilde{w} = (w_1^1, \dots, w_{n_1}^1, \dots, w_1^m, \dots, w_{n_m}^m) \in \mathcal{W}$ satisfying the following conditions:

$$\sum_{j=1}^{n_1} w_j^1 + \sum_{j=1}^{n_2} w_j^2 + \dots + \sum_{j=1}^{n_m} w_j^m = 1, \quad (12)$$

$$w_j^i \geq 0, j = 1, \dots, n_i; i = 1, \dots, m, \quad (13)$$

$$w_1^i \leq w_2^i \leq \dots \leq w_{n_i}^i, i = 1, \dots, m, \quad (14)$$

define a risk statistic

$$\hat{\rho}(\tilde{x}) := s \cdot \sup_{\tilde{w} \in \mathcal{W}} \left\{ \sum_{j=1}^{n_1} w_j^1 x_{(j)}^1 + \sum_{j=1}^{n_2} w_j^2 x_{(j)}^2 + \dots + \sum_{j=1}^{n_m} w_j^m x_{(j)}^m \right\},$$

$$\forall \tilde{x} = (\tilde{x}^1, \tilde{x}^2, \dots, \tilde{x}^m) \in \mathbb{R}^n, \quad (15)$$

where $(x_{(1)}^i, \dots, x_{(n_i)}^i)$ is the order statistics of $\tilde{x}^i = (x_1^i, \dots, x_{n_i}^i)$ with $x_{(n_i)}^i$ being the largest, $i = 1, \dots, m$. Then the risk statistic defined in Equation (15) is a law-invariant coherent risk statistic.

(ii) If $\hat{\rho}$ is a law-invariant coherent risk statistic, then there exists a set of weights $\mathcal{W} = \{\tilde{w}\} \subset \mathbb{R}^n$ with each $\tilde{w} \in \mathcal{W}$ satisfying Equations (12), (13), and (14), such that

$$\hat{\rho}(\tilde{x}) = s \cdot \sup_{\tilde{w} \in \mathcal{W}} \left\{ \sum_{j=1}^{n_1} w_j^1 x_{(j)}^1 + \sum_{j=1}^{n_2} w_j^2 x_{(j)}^2 + \dots + \sum_{j=1}^{n_m} w_j^m x_{(j)}^m \right\},$$

$$\forall \tilde{x} = (\tilde{x}^1, \tilde{x}^2, \dots, \tilde{x}^m) \in \mathbb{R}^n. \quad (16)$$

Proof. See Ref. 40 (for the case of $m = 1$, see also Ref. 55). Q.E.D.

By Theorem 1 and 3, we see the main differences between natural risk statistics and coherent risk measures:

1. Coherent risk measures are in general not robust, because every law-invariant

coherent risk statistic assigns larger weights to larger observations, but assigning larger weights to larger observations is apparently sensitive to small changes in the data. In fact, the finite sample breakdown point (see Ref. 22 for the definition) of any law-invariant coherent risk statistic is equal to $1/(1+n)$, that is, one single contamination sample can cause unbounded bias.

2. VaR and VaR with scenario analysis are not law-invariant coherent risk statistics, but are natural risk statistics.
3. Law-invariant coherent risk statistics, which exclude the use of robust statistics, are a subclass of natural risk statistics.

Comparison with Insurance Risk Measures

Similarly, we can define the insurance risk statistics, the data-based versions of insurance risk measures, as follows:

Definition 4. A risk statistic $\hat{\rho} : \mathbb{R}^n \rightarrow \mathbb{R}$ is called an insurance risk statistic, if it satisfies the following Axiom F1–F4.

Axiom F1. Scenario-wise permutation invariance: the same as Axiom C4.

Axiom F2. Monotonicity: $\hat{\rho}(\tilde{x}) \leq \hat{\rho}(\tilde{y})$, if $\tilde{x} \leq \tilde{y}$.

Axiom F3. Scenario-wise comonotonic additivity: $\hat{\rho}(\tilde{x} + \tilde{y}) = \hat{\rho}(\tilde{x}) + \hat{\rho}(\tilde{y})$, if $\tilde{x}$ and $\tilde{y}$ are scenario-wise comonotonic.

Axiom F4. Scale normalization: $\hat{\rho}(\mathbf{1}) = 1$.

We have the following representation theorem for insurance risk statistics.

Theorem 4. $\hat{\rho}$ is an insurance risk statistic if and only if there exists a single weight $\tilde{w} = (w_1^1, \dots, w_{n_1}^1, \dots, w_1^m, \dots, w_{n_m}^m) \in \mathbb{R}^n$ with $w_j^i \geq 0$ for $\forall i, j$ and $\sum_{i=1}^m \sum_{j=1}^{n_i} w_j^i = 1$, such that

$$\hat{\rho}(\tilde{x}) = \sum_{j=1}^{n_1} w_j^1 x_{(j)}^1 + \sum_{j=1}^{n_2} w_j^2 x_{(j)}^2 + \dots + \sum_{j=1}^{n_m} w_j^m x_{(j)}^m, \\ \forall \tilde{x} = (\tilde{x}^1, \tilde{x}^2, \dots, \tilde{x}^m) \in \mathbb{R}^n, \quad (17)$$

where $(x_{(1)}^i, \dots, x_{(n_i)}^i)$ is the order statistics of $\tilde{x}^i = (x_1^i, \dots, x_{n_i}^i)$, $i = 1, \dots, m$.

Proof. See Ref. 40. Q.E.D.

By Theorem 1 and 4, we see the main differences between natural risk statistics and insurance risk statistics:

1. Insurance risk statistics are less robust to model misspecification than natural risk statistics, because they do not incorporate multiple priors of probability distributions on the set of scenarios, and they do not incorporate multiple subsidiary risk statistics for each scenario.
2. Insurance risk statistics do not include VaR with scenario analysis such as the ones defined in Equations (2), (3), and (4), although they include VaR as a special case. However, VaR with scenario analysis are special cases of natural risk statistics.
3. Insurance risk statistics, which incorporate only one prior, are a subclass of natural risk statistics.

CONCLUSION

We propose new data-based risk measures called *natural risk statistics* that are characterized by a new set of axioms. The new axioms only require subadditivity for comonotonic random variables, which is consistent with prospect theory in economics. Natural risk statistics include (i) TCM, which is more robust than TCE suggested by coherent risk measures; (ii) VaR with scenario analysis, in particular, the Basel II risk measures, as special cases. Therefore, natural risk statistics provide a theoretical basis for using VaR with scenario analysis in external regulation.

We emphasize that an external risk measure should be robust with respect to model misspecification and small changes in the data in order for the consistent implementation of the risk measure across all the

relevant institutions. In contrast to coherent risk measures which are generally not robust, natural risk statistics include a subclass of robust risk statistics that are suitable for external regulation.

ROBUST OFFLINE SINGLE-MACHINE SCHEDULING PROBLEMS

BITA TADAYON

University of Florida,
Gainesville, FL

J. COLE SMITH

Clemson University, Clemson, SC

The single-machine scheduling problems (SMSPs) that we examine in this article seek to schedule nonpreemptive jobs on a single machine, which is capable of performing only one task at a time. Defining J as the set of all jobs, each job $j \in J$ is typically associated with data attributes such as processing time (p_j), weight (w_j), and due date (d_j). The objective of a schedule depends on the completion time (C_j) of each job $j \in J$. Define L_j (lateness) as $C_j - d_j$, T_j (tardiness) as $\max\{0, C_j - d_j\}$, and U_j as a binary indicator value equal to 1 if and only if $C_j - d_j > 0$. Common single-machine scheduling objectives include minimizing total completion time ($\sum_{j \in J} C_j$), total weighted completion time ($\sum_{j \in J} w_j C_j$), and the number of late jobs ($\sum_{j \in J} U_j$). In addition, defining $L_{\max} = \max_{j \in J} \{L_j\}$ (and $T_{\max}$ and $C_{\max}$ analogously), other common objectives include minimizing $L_{\max}$, $T_{\max}$, and $C_{\max}$. (The latter objective is also referred to as *makespan*.)

Deterministic scheduling problems assume that the exact values of all parameters are known. As a result, it is straightforward to calculate the job completion times and objective function value corresponding to each sequence. Moreover, each problem listed above is polynomially solvable using deterministic data [1–3], assuming that the release times for all jobs are zero.

Owing to the variability of process and environmental data, uncertainty is common in many practical scheduling problems. Therefore, several researchers have developed methods to hedge against data uncertainty in scheduling problems.

Reactive (online) scheduling deals with adjusting job schedules as data is realized in order to reduce the effect of disruptions and unpredicted delays. Using this approach, the scheduler generates initial schedules without considering uncertainty, and then revises the schedule as disruptions occur. Online scheduling is useful for situations in which limited information about uncertain data is available in advance, and it is practical for the scheduler to dynamically adjust the schedules. This reactive approach can accommodate a wide variety of disruptions (such as machine breakdowns, process interruptions, or parameter value variations) and is suitable for problems in which disruptions are difficult to predict. For example, process scheduling in an operating system can be modeled as an online scheduling problem as the operating system typically does not know the execution time of a process before its completion, and it is possible for the operating system to interleave the execution of different tasks by temporarily interrupting a task and resuming its execution at a later time (preemption). Another example regards the scheduler component of a web server, where the number of users and the length of each user's tasks is difficult to predict. See Ref. 4 for an overview of online scheduling and a survey of results obtained in this area, and [5] for an example of online single-machine scheduling.

However, it is not always realistic to assume that schedules can be revised after disruptions. In these situations, a predictive (offline) scheduling approach prescribes solutions that are relatively insensitive to changes in input data. An implicit assumption made in offline scheduling is that all uncertain data values are realized after the decisions have been made. Stochastic programming and robust optimization are two important offline modeling schemes that have been applied for solving several scheduling problems under uncertainty. Stochastic optimization, which was first

introduced by Dantzig [6], assumes knowledge of data probability distributions. This method seeks to optimize the expected objective function value, while ensuring that constraints are satisfied at least with sufficiently high probability. We refer the interested reader to textbooks [7–9] and the references therein for stochastic programming background. Pinedo and Schrage [10] present a survey of stochastic optimization applications in solving scheduling problems.

The expected objective function value is not the only metric by which schedules are evaluated when data is uncertain. Sarin *et al.* [11] study the problem of selecting schedules based both on the expectation of their objective function values and the variation of their objectives, given distributions on the uncertain parameter values. Stochastic scheduling studies also consider optimization metrics such as value-at-risk (VaR) [12] or conditional-value-at-risk (CVaR) [13]. A related strategy may instead associate so-called chance constraints with stochastic scheduling problems. The work of van den Akker and Hoogeveen [14] examines problems with due dates and requires that the probability of finishing each job by its due date be sufficiently large (or else the job is counted as late). They seek to determine sequences that minimize the number of late jobs—as defined in the chance-constrained sense—given various assumptions on the job processing time distributions. Deng and Shen [15] consider a related problem in a multiserver setting, where each server has some maximum time past which it should not operate. If a server operates past its maximum time, the server is said to be working overtime. The challenge is to schedule jobs, each of which has a certain release time and stochastic processing time, to servers in order to minimize scheduling costs, while ensuring that the probability that a server works overtime is sufficiently small.

Robust optimization is an alternative approach for dealing with uncertain data [16, 17]. In robust optimization, data uncertainty is usually represented by continuous or discrete uncertainty sets, and the solution must remain feasible with respect to any

possible data outcome within the uncertainty set. Two main factors motivate the use of robust optimization. First, it is not always possible to estimate data probability distributions with desired precision. Second, in stochastic programming, the problem size increases drastically with the number of uncertain parameters, which induces substantial computational challenges. Another essential difference between the stochastic programming and robust optimization approaches is that stochastic programming models typically aim at optimizing expected system performance, while robust optimization models focus on guaranteeing a minimum quality for the solution in the worst case.

In the deterministic scheduling literature, problems are classified into different categories based on the machine environment (α), job characteristics (β), and the optimization criterion (γ), and we assume that the exact values of all parameters are known. Single machine (1), m -machine flow shop (F_m), and m -machine job shop (J_m) are examples of common machine environments (α), while having precedence relations between jobs (prec) and having families of jobs with similar characteristics (fml) are examples of job characteristics (β). Any minimization criterion, such as $C_{\max}$, $\sum C_j$, and $\sum U_j$, is an example of γ . Accordingly, we can specify every deterministic scheduling problem using Graham’s notation $\alpha|\beta|\gamma$ suggested in Ref. 18. In robust optimization, however, we assume that different job-related parameters such as p_j , d_j , and w_j are uncertain, and we optimize with respect to the worst-case data realization using a min–max objective. Therefore, we also specify the uncertain parameters in the notation, denoted by η . We specify the robustness measure for the problem, ν , which we explain in detail in the section titled “Robustness Measures” and describe a robust scheduling problem using the notation $\text{MinMax}_\nu(\alpha|\beta|\gamma, \eta)$.

In this article, we review robust optimization techniques that have been used for solving standard scheduling problems under uncertainty. Note that the majority of research in this area is focused on SMSPPs. Thus, we explore and classify the literature

of robust SMSP, while addressing some other standard scheduling problems that have been investigated.

The remainder of this article is organized as follows. In the section titled “Robustness and Uncertainty Definitions,” we describe different robustness criteria and uncertainty representations used in the robust optimization literature and address the use of each method in scheduling. Then in the section titled “Robust Single-Machine Scheduling Literature Classification,” we discuss the details of existing research in the area of robust SMSP, classify them according to the categories presented in section titled “Robustness and Uncertainty Definitions,” and explore the existing gaps and open problems. We then address related robust scheduling results in the section titled “Robust Optimization in Other Scheduling Problems” and conclude in the section titled “Conclusion and Open Research Questions.”

ROBUSTNESS AND UNCERTAINTY DEFINITIONS

To define a robust scheduling problem, we need to represent the potential values of uncertain parameters in the problem and specify a measure by which we evaluate the robustness of a particular solution. In this section, we present the most common robustness measures and uncertainty representations for robust optimization in general and for robust scheduling in particular. We also discuss the benefits, limitations, and potential applications for each scheme.

Define a sequence, π , as a permutation of jobs and denote the set of all possible permutations by Π . A scenario, ϕ , is a particular realization of uncertain parameters, where Φ represents the (possibly infinite-cardinality) set of all possible scenarios. Let Z_π^ϕ be the objective function value of job sequence π under data realization ϕ . Define Z^ϕ as the best achievable (optimal) objective function value when data scenario ϕ is realized. We use this notation to present robustness and uncertainty definitions in the following two subsections.

Robustness Measures

We discuss the three most common robustness measures that arise in the scheduling field: absolute robustness, robust deviation, and relative robust deviation [19]. (See also Sabuncuoglu and Goren [20] for a more detailed classification for possible robustness and stability measures, along with applications of some measures in solving robust SMSPs.)

Absolute robustness seeks to minimize the maximum objective function value over all scenarios. That is, when dealing with the absolute robustness measure, we associate a worst-case scenario with each possible job sequence and select a sequence whose worst-case objective value is minimum among all feasible sequences. We can mathematically state absolute robustness as $\min_{\pi \in \Pi} \max_{\phi \in \Phi} Z_\pi^\phi$. This measure is particularly useful for situations in which one seeks to guarantee at least a certain quality for the solution over all possible scenarios. In our modified Graham’s notation, the subscript ν is blank for the absolute robustness case, as this problem directly minimizes the maximum possible scheduling objective that can occur (and as such is the “default” robustness measure).

To understand the *robust deviation* measure, we first introduce the concept of regret. In the context of robust scheduling, a decision-maker chooses a schedule before observing the data values. After the data is observed, the decision-maker’s regret is given by the difference between his/her chosen schedule’s objective and the objective of the retrospective optimal solution, that is, the optimal solution given knowledge of the data outcome. Robust deviation seeks to minimize the largest possible regret and can be stated as $\min_{\pi \in \Pi} \max_{\phi \in \Phi} (Z_\pi^\phi - Z^\phi)$. Minimizing robust deviation yields a schedule whose performance, compared to the corresponding optimal performance, is relatively insensitive to data realization. Solutions that minimize robust deviation can also be interpreted as *uniformly suboptimal* solutions, that is, ϵ -optimal solutions for all data realizations, with ϵ as small as possible. In our scheduling problem notation, $\nu = \text{dev}$ for this case.

Relative robust deviation minimizes the maximum relative (or percentage) deviation from optimality, that is, $\min_{\pi \in \Pi} \max_{\phi \in \Phi} ((Z_{\pi}^{\phi} - Z^{\phi})/Z^{\phi})$. In fact, relative robust deviation is a normalized robust deviation measure that seeks to minimize the relative regret in the problem. As the value of relative regret only depends on the ratio of objective values, it can be used to create benchmarks to compare the quality of different problems' solutions. In the case of relative robust deviation, we denote $\nu = \text{rel}$.

Robust deviation and relative robust deviation measures are appropriate for environments in which the quality of solutions are evaluated after the data is realized. In such cases, the (relative) deviation of the selected decision from the optimal decision for the realized scenario is a plausible quality measure. These measures may be particularly important in the context of highly competitive markets, where a firm needs to have a satisfactory performance compared to its competitors, under any potentially realizable scenario [19].

Before proceeding, it is useful to emphasize the robust optimization paradigm, and how the objectives and uncertainty sets interact in the optimization scheme. These problems can be described as Stackelberg games [21], which involve a leader and a follower. In the robust optimization context, the leader determines a schedule with the objective of minimizing an objective. The follower, with knowledge of the leader's selected job permutation, selects data values to make the solution as poor as possible, either by maximizing the objective function (absolute robustness) or regret (robust deviation or relative robust deviation). The leader anticipates the follower's optimal action and selects a schedule that minimizes the largest objective the follower can obtain.

Example 1 To illustrate the difference between robustness measures, consider an example in which we seek to find a two-job schedule that minimizes the total completion time, where $p_1 \in [4, 5]$ and $p_2 \in [1, 6]$. If we apply the absolute robustness measure, the worst-case scenario for any sequence occurs when $p_1 = 5$ and $p_2 = 6$. Therefore,

the robust optimal solution is obtained by scheduling job 1 before job 2 (sequence (1, 2)). However, when robust deviation is applied, the largest regret value equals 4 for sequence (1, 2) (when $p_1 = 5$ and $p_2 = 1$) and equals 2 for sequence (2, 1) (when $p_1 = 4$ and $p_2 = 6$). Therefore, scheduling job 2 before job 1 optimizes robust deviation. Note that using relative robust deviation for this instance also results in sequence (2, 1) being optimal (the largest relative regret value equals $4/7$ for sequence (1, 2) and $2/14$ for sequence (2, 1)). However, robust deviation and relative robust deviation measures may result in different optimal solutions in other instances. For example, suppose that we modify the above example by letting $p_1 \in [4, 5]$ and $p_2 \in [2, 8]$. Given sequence (1, 2), the largest absolute regret value (3) is obtained when $p_1 = 5$ and $p_2 = 2$. The objective of sequence (1, 2) is 12, while the optimal objective value for this scenario is 9. Sequence (2, 1), on the other hand, results in a maximum regret value of 4, and therefore sequence (1, 2) is preferable with respect to the robust deviation measure. However, the relative regret value is $3/9$ for sequence (1, 2) and $4/16$ for sequence (2, 1). Thus, sequence (2, 1) is optimal under the relative robust deviation measure.

Note in Example 1 that the p_1 and p_2 values are confined to simple, independent intervals, that is, the follower maximizes over a rectangular feasible region. More research has recently been performed in this area to explore the impact of using alternative feasible regions for the follower, as described in the section titled "Uncertainty Representation."

Uncertainty Representation

In the robust optimization literature, several methods of expressing uncertain parameter values have been proposed. In this section, we discuss four main methods of uncertainty representation, present benefits and drawbacks of each method, and address some applications of each method in robust scheduling.

The original method of representing uncertainty in robust optimization problems

was developed by Soyster [22]. Soyster assumes that each uncertain parameter, independent of all the others, can take on any values within a continuous interval and proposes a linear optimization model to solve the problem. These uncertainty sets are given the label *interval uncertainty*. The simplicity of this method and its resulting formulations motivate its extensive application in robust scheduling problems. See Refs 23–26 as examples of using interval uncertainty to represent the values of SMSP parameters having different optimization criteria.

Note that if data is represented by interval uncertainty, and we seek to minimize absolute robustness, setting all parameters to their worst-case values will generate a worst-case scenario corresponding to any sequence of jobs. Therefore, robust SMSPs having the absolute robustness criterion under interval uncertainty is equivalent to a deterministic SMSP in which all data elements take on their worst-case values. However, generating a worst-case scenario when either the robust deviation or the relative robust deviation measure is applied is less obvious in general. Recall that in Example 1, robust deviation and relative robust deviation were maximized by setting either p_1 to its maximum value and p_2 to its minimum value, or vice versa. This is more complex than simply setting processing times to their largest possible values.

Although interval uncertainty results in simple robust formulations for several problems, it tends to generate schedules that are too conservative in the case of absolute robustness. Ben-Tal and Nemirovski [27–29] and El-Ghaoui and Lebret [30] and El-Ghaoui *et al.* [31] address this issue and introduce a method to reduce the level of conservatism by confining the data to belong to uncertainty sets in the form of ellipsoids. They propose efficient algorithms to solve the resulting convex optimization problems.

Bertsimas and Sim [32, 33] propose *budgeted uncertainty* as an alternative approach to control the level of conservatism for general robust optimization problems. This method assumes that while all uncertain parameters are bounded within a specified

interval, the total amount of variation in parameters from their “ideal values” is limited. Using this method to represent uncertain objective function and constraint coefficients of an optimization problem, they propose a robust programming problem of moderately larger size. The authors prove that using budgeted uncertainty, a robust linear programming problem can still be solved as a linear program, and the robust counterpart of a polynomially solvable 0–1 linear optimization problem remains polynomially solvable.

To the best of our knowledge, the budgeted uncertainty model is applied to robust SMSP in only one paper [34], which we discuss in the section titled “Robust Single-Machine Scheduling Literature Classification.” However, budgeted uncertainty has been directly applied in several other scheduling problems in the area of chemical process scheduling, as we discuss in the section titled “Robust Optimization in Other Scheduling Problems.”

A disadvantage of interval uncertainty models is that they do not capture correlations among data. Budgeted or ellipsoidal uncertainty can implicitly capture some correlations by limiting total parameter deviation from their norms. Moreover, because these modeling strategies essentially employ strong duality principles to the follower’s maximization problem, it is also generally easy to obtain robust formulations for the case in which uncertainty sets can be expressed as a convex set. Still, when such a convex set is not easy to obtain, or correlations among parameters yield a nonconvex uncertainty set, an alternative way of modeling uncertainty is needed. One way to represent these correlations is to enumerate all possible scenarios and represent uncertain parameters as a set of discrete scenarios for their numerical values. We refer to this method as *scenario uncertainty*. In the robust SMSP literature, using scenario uncertainty is common [35–38]. This method allows the decision-maker to consider the relationship between all uncertain factors in the scheduling environment and include all possible cases in the model. It also maintains control over the level of conservatism in the problem. However, this approach potentially

requires enumeration of a large number of data outcomes, which is computationally intractable in some cases.

Example 2 To illustrate the foregoing concepts, consider a three-job problem in which we seek to minimize weighted completion time under the absolute robustness objective, with uncertainty in the processing times (problem $\text{MinMax}(1 \parallel \sum w_j C_j, p_j)$). This example focuses on the case of budgeted uncertainty. In particular, defining $\hat{p}_1 = 8$, $\hat{p}_2 = 7$, and $\hat{p}_3 = 4$, the uncertainty set constraints bounding the p values are given by:

$$|p_j - \hat{p}_j| \leq 2, \forall j = 1, 2, 3, \text{ and } \sum_{j=1}^3 \frac{|p_j - \hat{p}_j|}{\hat{p}_j} \leq 0.6. \quad (1)$$

That is, absolute deviation from the “ideal” processing times ($\hat{p}$) is no more than 2, and the total percentage deviation is limited by 0.6. (This is one particular example of budgeted uncertainty; it is also possible to have individual deviations limited as a percentage of the ideal processing times, and/or the left-hand-side of the total deviation constraint refer to absolute deviation rather than percent deviation.) The weights for these jobs are deterministic and given by

$$w_1 = 9, w_2 = 7, w_3 = 4. \quad (2)$$

For the case of absolute robustness, Table 1 shows the six feasible sequences. In addition, for each sequence, the associated worst-case p values are depicted, alongside the resulting objective. Note that there are two sequences—(1, 2, 3) and (1, 3, 2)—that would be optimal in the deterministic version of the problem, where $p_j = \hat{p}_j$ for all j . Only the latter is optimal when minimizing absolute robustness.

Table 1 shows that each worst-case p vector is an extreme point to the uncertainty set given by Equation 1. This is as expected, because the follower (inner maximization) problem seeks to optimize a linear function over a polyhedral set. Another conjecture might be that an optimal sequence must correspond to some schedule generated

Table 1. Minimization of Absolute Robustness in Example 2

Sequence	Worst-Case Values			Objective
	p_1	p_2	p_3	
(1, 2, 3)	10	9	4.257	316.029
(1, 3, 2)	10	9	4.257	309.829
(2, 1, 3)	10	9	4.257	327.029
(2, 3, 1)	10	9	4.257	325.343
(3, 1, 2)	10	7	5.4	317
(3, 2, 1)	8	9	5.257	321.143

Optimal sequence: (1, 3, 2), objective 309.827

according to the weighted shortest processing time (WSPT) rule, where processing times correspond to the ideal processing times $\hat{p}$. (In the case above, the optimal sequence of (1, 3, 2) corresponds to one of the two WSPT sequences.) However, suppose that we now take $w_3 = 4 + \Delta$. As Δ becomes negative, the WSPT rule would schedule the jobs in order (1, 2, 3), which is suboptimal for the absolute robustness problem above. It turns out that for any nonpositive Δ , the worst-case p values for sequences (1, 2, 3) and (1, 3, 2) remain as depicted in Table 1. Thus, for $\Delta \leq 0$, the worst-case costs for these sequences are given by:

$$\text{Cost for sequence (1, 2, 3)}: 316.028 - 23.257\Delta$$

$$\text{Cost for sequence (1, 3, 2)}: 309.827 - 14.257\Delta. \quad (3)$$

For $\Delta < -0.689$, sequence (1, 2, 3) replaces (1, 3, 2) as the optimal robust solution.

As a final observation, note that the worst-case p values do change as Δ becomes positive. For sequence (1, 3, 2), the worst-case p values change from $p = (10, 9, 4.257)$ for $\Delta \leq 1.25$ to $p = (10, 7, 5.4)$ for $\Delta \geq 1.25$. (However, at $\Delta = 1.25$, sequence (3, 1, 2) becomes optimal, as sequence (1, 3, 2) is optimal only up to $\Delta < 0.81$.)

Example 3 We next reconsider Example 2 for problem $\text{MinMax}_v(1 \parallel \sum w_j C_j, p_j)$, for v corresponding to robust deviation and relative robust deviation. All data for this example is the same as in Example 2. Table 2 lists all six possible sequences.

Table 2. Minimization of Robust Deviation in Example 3

Sequence	Worst-Case Values			Objective	Retrospective Optimal		Robust Deviation
	p_1	p_2	p_3		Sequence	Objective	
(1, 2, 3)	10	7	2.6	287.4	(3, 2, 1)	254	33.4
(1, 3, 2)	10	5	3.743	276.173	(2, 3, 1)	238.659	37.514
(2, 1, 3)	6	9	3.743	272.972	(1, 3, 2)	224.173	48.799
(2, 3, 1)	6	9	4.257	289.341	(1, 3, 2)	229.827	59.514
(3, 1, 2)	8	5	5.257	268.14	(2, 1, 3)	225.028	43.112
(3, 2, 1)	6	7	5.4	274	(1, 2, 3)	218.6	55.4

Optimal sequence: (1, 2, 3), objective 33.4

For each sequence, a worst-case set of p values is given that maximizes robust deviation. In column *objective*, the resulting objective from the chosen sequence is given. The *retrospective optimal* columns depict the optimal sequence corresponding to the worst-case p values, along with the objective corresponding to that sequence. The *robust deviation*, or regret, of the solution is shown in the last column, which is given by the difference in the objective corresponding to the original sequence and that corresponding to the retrospective optimal solution. Note that in this case, some components of the worst-case p values may be smaller than their ideal values, in order to force a maximum difference between the objective of the initial sequence and that of the retrospective optimal solution.

For the relative robust deviation case, Table 3 provides an optimization analysis similar to that in Table 2. Sequence (1, 2, 3) remains optimal in this case. Interestingly, however, both the worst-case set of p values and the retrospective optimal solution

corresponding to (1, 2, 3) changes in the relative robust deviation case. With respect to sequence (2, 3, 1), p_3 equals 4.257 in the robust deviation case and equals 3.743 in the relative robust deviation case. All worst-case p values and retrospective sequences remain unchanged for the other four possible sequences.

Finally, while it is not a surprise that sequence (1, 2, 3) would be optimal for both the robust deviation and relative robust deviation measures, the same sequence need not optimize both of these measures in general. For instance, suppose that we revise $w_3 = 4.35$. In this case, sequence (1, 2, 3) is no longer optimal under either objective. Table 4 shows that robust deviation is minimized by sequence (3, 1, 2), while relative robust deviation is minimized by sequence (1, 3, 2). Importantly, for these two sequences, the same p vector that maximizes robust deviation also maximizes relative robust deviation. Hence, we only report one worst-case set of p values in Table 4 for each sequence, even though as demonstrated above, different p values may correspond to the same initial

Table 3. Minimization of Relative Robust Deviation in Example 3

Sequence	Worst-Case Values			Objective	Retrospective Optimal		Robust Deviation
	p_1	p_2	p_3		Sequence	Objective	
(1, 2, 3)	8	7.7	2	252.7	(3, 1, 2)	221.9	0.139
(1, 3, 2)	10	5	3.743	276.173	(2, 3, 1)	238.659	0.157
(2, 1, 3)	6	9	3.743	272.972	(1, 3, 2)	224.173	0.218
(2, 3, 1)	6	9	3.743	282.659	(1, 3, 2)	224.173	0.261

(3, 2, 1)	6	7	5.4	274	(1, 2, 3)	218.6	0.253

Optimal sequence: (1, 2, 3), objective 0.139

Table 4. Example Illustrating Different Optimal Solutions to Robust Deviation and Relative Robust Deviation Objectives when $w_3 = 4.35$

Sequence	Worst-Case Values			Objective	Retrospective Optimal		Robust Deviation	Relative Robust Deviation
	p_1	p_2	p_3		Sequence	Objective		
(1, 3, 2)	10	5	3.743	280.983	(2, 3, 1)	241.719	39.264	0.162
(3, 1, 2)	8	5	5.257	269.98	(2, 1, 3)	231.42	38.56	0.167

Optimal sequence: (3, 1, 2) for robust deviation and (1, 3, 2) for relative robust deviation

sequence depending on whether robust deviation or relative robust deviation is being considered.

ROBUST SINGLE-MACHINE SCHEDULING LITERATURE CLASSIFICATION

In this section, we review the robust single-machine scheduling literature and classify existing research in this area according to their robustness measure definition and uncertainty representation. Kasperski [39] summarizes some of the results obtained in the robust SMSP literature for different cases (specified by a robustness measure and an uncertainty representation) and introduces open cases in this area. A short survey of the results is also presented in Ref. 40. Here, we provide an updated discussion of the results obtained in each category of SMSPs.

As stated in the section titled “Uncertainty Representation,” the case of absolute robustness when dealing with continuous intervals of uncertainty can be equivalently solved as a deterministic problem and therefore is out of the scope of this study. However, when parameter values are constrained beyond their simple interval bounds, as in budgeted uncertainty, there is no obvious equivalent deterministic formulation for the problem. Tadayon and Smith [34] define three alternative uncertainty sets for the absolute robust SMSP when processing time values are presented as independent continuous intervals. In uncertainty sets 1, 2, and 3, they, respectively, require the total delay, the number of delayed jobs, and the total ratio by which the processing times are increased to be no more than a

budget value. They study the complexity of the problem $\text{MinMax}(1 \| Z, p_j)$, where $Z \in \{\sum C_j, \sum w_j C_j, L_{\max}, T_{\max}, \sum U_j\}$ under each uncertainty set, propose exact algorithms for polynomially solvable problems, and present mixed-integer programming formulations for the NP-hard problems and the ones having an unknown complexity.

Absolute robust SMSP in presence of scenario uncertainty has been studied in several papers. Yang and Yu [41] prove that problem $\text{MinMax}_v(1 \| \sum C_j, p_j)$ with scenario uncertainty is NP-hard for all three robustness measures (even in the special case having only two scenarios). They also present an exact dynamic programming algorithm with exponential complexity and two polynomial-time heuristics to solve this robust SMSP.

Aloulou and Della Croce [35] study several other absolute robust SMSPs with scenario uncertainty in different job-related parameters. When the scheduler seeks to minimize the number of late jobs, they prove that problems $\text{MinMax}(1 \| \sum U_j, p_j)$ and $\text{MinMax}(1 \| \sum U_j, p_j, d_j)$ are NP-hard, but the case of $\text{MinMax}(1 \| \sum U_j, d_j)$ is still open. In addition, when the objective function seeks to minimize $f_{\max} \in \{C_{\max}, L_{\max}, T_{\max}\}$ and precedence relations between jobs in the sequence are allowed, they propose polynomial algorithms for solving the problem in which p_j , d_j , or both are expressed as a set of discrete scenarios. In addition, they prove that problem $\text{MinMax}(1 \| \sum w_j C_j, w_j)$ with scenario uncertainty is NP-hard. (The NP-hardness of $\text{MinMax}(1 \| \sum w_j C_j, p_j)$ also follows from the NP-hardness of $\text{MinMax}(1 \| \sum C_j, p_j)$, which was proved in Ref. 41.)

Mastrolilli *et al.* [38] seek to generate approximation schemes for problem $\text{MinMax}(1 \parallel \sum w_j C_j, w_j, p_j)$. They prove that the problem cannot be approximated within $\mathcal{O}(\log^{1-\epsilon} n)$ for any $\epsilon > 0$, unless quasi-polynomial algorithms exist for NP. For the special case of unweighted jobs, they propose a two-approximation algorithm for solving $\text{MinMax}(1 \parallel \sum C_j, p_j)$ and prove that the problem is NP-hard to approximate within a factor less than 6/5.

In contrast to the extensive application of absolute robustness in the robust optimization literature, robust deviation has been investigated more widely in the SMSP literature. (This difference may in part be due to the ease of solving absolute robustness problems under the interval uncertainty model.) When independent continuous intervals are used to represent uncertain processing times, Lebedev and Averbakh [42] prove that the general case of problem $\text{MinMax}_{\text{dev}}(1 \parallel \sum C_j, p_j)$ is NP-hard; however, they show that when all intervals of uncertainty have the same center, the problem can be solved polynomially (in $\mathcal{O}(n \log n)$ time) if the number of jobs is odd, and is NP-hard otherwise. Montemanni [26] presents the first mixed-integer linear programming formulation for problem $\text{MinMax}_{\text{dev}}(1 \parallel \sum C_j, p_j)$ with interval uncertainty and translates some preprocessing rules into valid inequalities.

Kasperski and Zielinski [43] prove that any minmax robust deviation SMSP with total completion time criterion and interval uncertainty, whose equivalent deterministic problem is polynomially solvable, can be approximated within a factor of 2. A more general case of this problem with weighted sum of completion time criterion ($\text{MinMax}_{\text{dev}}(1 \parallel \sum w_j C_j, p_j)$) has been studied in Ref. 44 in which some dominance relations are introduced and a heuristic algorithm is proposed to find a good nondominated sequence.

Robust deviation in the case of interval uncertainty is also considered in Refs 23, 24, and 25 for different SMSPs. Averbakh [23] proves that $\text{MinMax}_{\text{dev}}(1 \parallel \max\{w_j T_j\}, w_j)$ is polynomially solvable by presenting an $\mathcal{O}(n^3)$ algorithm for the problem. Kasperski

[24] proposes a polynomial algorithm (with $\mathcal{O}(n^4)$ complexity) for optimally solving $\text{MinMax}_{\text{dev}}(1 \parallel \text{prec}|L_{\max}, p_j, d_j)$. Lu *et al.* [25] define a specific SMSP with total completion time objective function in which jobs are grouped into families and a sequence-dependent family setup time exists. They prove that when both job processing times and family setup times are presented as intervals of uncertainty, minimizing robust deviation in the corresponding problem is NP-hard. They then propose a simulated annealing-based algorithm to find good quality solutions for the problem.

Several researchers study robust deviation in SMSPs in which parameters are presented as discrete scenarios. Daniels and Kouvelis [36] examine problems $\text{MinMax}_{\text{dev}}(1 \parallel \sum C_j, p_j)$ and $\text{MinMax}_{\text{rel}}(1 \parallel \sum C_j, p_j)$ when the uncertainty set consists of discrete scenarios for the p_j values. They prove that both problems are NP-hard and present some dominance relations that can be used to determine the relative job positions in a robust schedule. Then, they use these results to develop an exact branch-and-bound algorithm for solving the robust problem. They also present intuitive heuristic approaches and evaluate their efficiency and accuracy through a set of randomly generated instances. In addition, Daniels and Kouvelis prove that even when processing times are presented as independent continuous intervals, the worst-case scenario for each sequence π belongs to the finite set of extreme point scenarios (scenarios in which each parameter takes on its lower- or upper-bound values). According to this result, they claim that the formulations presented for scenario uncertainty are also valid for interval uncertainty.

Yang and Yu [41] present a different NP-hardness proof for the problem $\text{MinMax}_{\text{dev}}(1 \parallel \sum C_j, p_j)$. A more general problem with the weighted sum of completion time criterion (using the robust deviation measure and scenario uncertainty in job processing times) is studied in Ref. 37, where a set of valid inequalities for the convex hull of its feasible region is presented and is then utilized to design a cutting-plane algorithm for solving the problem.

To the best of our knowledge, relative robust deviation has been explicitly considered in only three SMSP papers so far. Averbakh [45] studies this measure of robustness for robust combinatorial optimization problems in general and for SMSP as a special case and proves that the problem $\text{MinMax}_{\text{rel}}(1 \parallel \sum C_j, p_j)$ with interval uncertainty is NP-hard. Daniels and Kouvelis state that the analysis, results, and solution methods presented in Ref. 36 for the case of robust deviation can be applied for the relative robust deviation measure with a slight modification. Finally, Yang and Yu [41] prove the NP-hardness of problem $\text{MinMax}_{\text{rel}}(1 \parallel \sum C_j, p_j)$ with scenario uncertainty.

ROBUST OPTIMIZATION IN OTHER SCHEDULING PROBLEMS

Although robust optimization has been most frequently studied for the single-machine scheduling environment, other scheduling problems have been also addressed in the literature. Moreover, the concept of robustness in some studies extends beyond the standard definitions presented earlier in this article and includes (i) the restriction that a schedule remains feasible with a certain probability [46], (ii) that a schedule guarantees a certain performance level [47, 48]), or (iii) the incorporation of different uncertainties in scheduling environments (e.g., unpredictable production interruptions [49]). In this section, we introduce some of the other areas of scheduling in which different variations of robust optimization have been applied to hedge against uncertainty in production environments.

Kouvelis *et al.* [50] apply a robustness definition similar to the one presented in this article to comply with uncertainty in a two-machine flow shop environment. They prove that problem $\text{MinMax}_{\text{dev}}(F_2 \parallel C_{\text{max}}, p_j)$ is NP-hard in the ordinary sense. They also discuss the properties of robust schedules and develop exact and heuristic solution approaches for the problem under both interval uncertainty and scenario uncertainty in job processing times. Kasperski *et al.* [51] strengthens the result obtained in Ref. 50

by proving that $\text{MinMax}_{\text{dev}}(F_2 \parallel C_{\text{max}}, p_j)$ in the case of scenario uncertainty is strongly NP-hard and inapproximable, even for two scenarios. They also prove that the absolute robust version of the problem is strongly NP-hard, but approximable with performance ratio of 2 and not $(4/3 - \epsilon)$ -approximable for any $\epsilon > 0$ if the number of scenarios is a known constant.

Although ellipsoidal and budgeted uncertainty have not yet been widely addressed in the robust single-machine scheduling literature, it has been applied to other scheduling problems, mainly in the area of chemical process scheduling. Production scheduling, as one of the most important problems in industrial plant operations, has been studied in several research papers. Short-term production scheduling seeks to determine an optimal assignment of available resources to production tasks over time while satisfying the production requirements at due dates. Depending on the plant layout and the sequence of tasks, process scheduling is usually in the form of a standard flow shop or job shop scheduling problem. Ierapetritou and Floudas [52] propose a mixed-integer linear programming formulation for this problem.

Li and Ierapetritou [53] consider uncertainty in parameter values in the formulation presented in Ref. 52. They examine interval, ellipsoidal, and budgeted uncertainty to formulate the robust process scheduling problem given uncertainties in product unit price, task processing times, and product demand values. They compare the three formulations by solving test instances from linear formulations using CPLEX and the ones from nonlinear formulations using the DICOPT solver via GAMS. The results of their computations show that the budgeted uncertainty model may yield the most appropriate formulation, owing to the fact that it does not increase the problem size substantially and maintains the linearity of the model.

Lin *et al.* [54] and Janak *et al.* [46] also consider data uncertainty in the process scheduling problem as formulated in Ref. 52. Uncertain parameters (price, processing times, and

demands) are presented as independent continuous intervals in Ref. 54 and as random variables with known probability distributions in Ref. 46. Janak *et al.* [46] define a robust solution to be one, that is, feasible in all constraints with a certain probability. Mathematical formulations for the robust problems are presented in both papers and the efficiency of models are investigated by solving test instances from linear formulations using CPLEX and from nonlinear models using DICOPT.

Li and Ierapetritou [55] review the process scheduling under uncertainty literature. They introduce robust optimization as one of the alternative approaches in dealing with uncertainty in process scheduling and address the main advances and challenges in this area of research. Verderame *et al.* [56] provide a broader overview of planning and scheduling problems under uncertainty, across multiple sectors. Although the objective function and constraints of the model vary greatly among different sectors, they address the common attribute of requiring a standard robustness definition and uncertainty representation across all areas.

Leon *et al.* [49] define a different type of uncertainty in a standard job shop environment in which disruptions occur randomly during the process. They seek to find a sequence of jobs, that is, robust under various disruption scenarios, assuming that preemption is not allowed (when a job's process is interrupted, it has to be restarted), the performance measure is makespan, and the order of jobs cannot be revised after interruptions occur. They define the robustness measure as a randomly weighted sum of the expected makespan and the expected difference between the actual makespan and the deterministic makespan (without interruptions). Because the effect of each disruption depends on the outcome of all previous disruptions, they compute the robustness measure only in the case of a single interruption. For the case of several disruptions, they develop a surrogate method and embed it in a genetic algorithm to generate relatively robust schedules.

A robust solution in some applications is defined as a solution that guarantees a certain level of performance under all possible data realizations. Daniels and Carrillo [47] define a β -robust solution as a job sequence that maximizes the likelihood of achieving a total completion time value no greater than a constant value in a SMSP with uncertain processing times. They assume that job processing times are independent random variables with known means and variances that can be represented as discrete scenarios. They prove that the problem is NP-hard and develop an exact branch-and-bound algorithm and a polynomial heuristic for solving the problem. Wu *et al.* [48] consider a similar problem with independent normally distributed processing time values and present three models: primal (maximizing the probability of obtaining a certain level of performance), dual (minimizing the level that can be achieved with a fixed probability), and hybrid. They determine the feasibility of each model for a set of randomly generated problems and study the effect of some dominance rules in solving the problems.

COMPLEXITY SUMMARY

Table 5 provides a summary of the results obtained in the robust SMSP literature. In this table, we specify the complexity of robust SMSP problems under each robustness measure (absolute robustness “abs. rob.,” robust deviation “rob. dev.,” and relative robust deviation “rel. rob. dev.”) and each uncertainty representation (budgeted uncertainty “budg. uncert.,” interval uncertainty “interval,” and scenario uncertainty “scenario”), as well as the reference from which the result is extracted. Each problem is specified by its objective function and uncertain parameter in the first column labeled as “(obj., param.).” Note that budgeted uncertainty has been considered only for the absolute robustness criterion. Among the results obtained in Ref. 34, we only include the ones about the first uncertainty set in this table, for the sake of brevity. The cells whose corresponding problems have not been yet studied in the literature are marked by “–.”

Table 5. Complexity Results for Robust SMSP

(obj., param.)	abs. rob.		rob. dev.		rel. rob. dev.	
	budg. uncert.	Scenario	Interval	Scenario	Interval	Scenario
$(\sum C_j, p_j)$	$\mathcal{O}(n \log n)$ [34]	NP-hard [41]	NP-hard [42]	NP-hard [36, 41]	NP-hard [45]	NP-hard [36, 41]
$(\sum w_j C_j, p_j)$	Open [34]	NP-hard [41]	NP-hard [42]	NP-hard [36, 41]	NP-hard [45]	NP-hard [36, 41]

CONCLUSION AND OPEN RESEARCH QUESTIONS

We categorize robust scheduling problems according to three main criteria: The deterministic scheduling problem (given by the Graham notational parameters α, β, γ) from which it is derived, the robustness measure (absolute robustness, robust deviation, or relative robust deviation), and the uncertainty sets that confine the uncertain parameters. In particular, the uncertainty sets typically consist either of a discrete set of scenarios that list every possible simultaneous data outcome, or a continuous region (described by a system of inequalities) to which the data can belong. In the latter case, interval uncertainty refers to the situation in which each data value is independently limited by a minimum and/or maximum value, whereas budgeted or ellipsoidal uncertainty are special cases in which inequalities confining the data parameters are more complex than simple upper or lower bounds.

From a modeling perspective, scenario uncertainty allows a decision-maker to capture correlations among data, but may require the enumeration of many scenarios to become practically useful. Budgeted or ellipsoidal uncertainty sets are convex and thus lose some modeling generality afforded by scenario uncertainty sets. However, these models implicitly capture many scenarios and often lead to more tractable robust optimization models.

Our work shows that many problems remain open for study, even under relatively simple continuous uncertainty sets. The challenge in solving robust optimization problems having continuous uncertainty sets is that the decision-maker must anticipate, and account for, data that depends on the chosen scheduling decision. In terms of Stackelberg (leader-follower) games, when the follower (inner maximization) problem is trivial, combining the outer minimization and inner maximization problems is sometimes straightforward, and the scheduling problems remain easy to solve. In other

cases, the inner maximization problem is more difficult, and leads to a far more complicated optimization problem. The complexity of several such problems remains open, even under budgeted or ellipsoidal uncertainty sets, with the absolute robustness objective. The theoretical investigation of these robust optimization problems, along with exact and heuristic schemes for solving them, constitutes a major challenge for scheduling researchers.

One of the most significant gaps in the literature of robust SMSP is the lack of results on continuous (noninterval) uncertainty representations, like budgeted uncertainty. Despite the extensive use of interval uncertainty and scenario-based uncertainty, there are disadvantages in using both. The assumption of having independent intervals for uncertain parameters results in extreme worst-case scenarios that rarely happen in practice. On the other hand, enumerating all possible cases in the case of scenario-based uncertainty may be computationally intensive. As budgeted uncertainty eliminates the shortcomings of these two methods, it has been widely applied in several robust optimization problems. Therefore, investigation of this uncertainty representation method in robust SMSP appears to be an important area for future investigation. In particular, when dealing with absolute robustness, several open problems have been listed in Ref. 34. In addition, the effect of uncertainty on the value of any parameter other than processing time is yet to be studied. For other robustness measures, budgeted uncertainty has not been addressed, which provides a great opportunity for a wide variety of research in this area.

Another opportunity for future research, which is evident from Table 5, is the application of robustness measures other than absolute robustness. Discovering the problems that remain polynomially solvable under these two robustness measures will shed light on the boundary between polynomially solvable and NP-hard robust scheduling problems. In addition to complexity analysis for unaddressed problems, designing efficient solution methods and

developing single-stage mathematical formulations for robust SMSP problems will be very beneficial. This effort could be further extended to address problems with more challenging scheduling objectives, such as total tardiness ($\sum_{j \in J} T_j$) and total weighted tardiness ($\sum_{j \in J} w_j T_j$), as well as objectives based on earliness and tardiness.

INTRODUCTION

Making any type of decision, from buying a car to siting a nuclear plant, from choosing the best student deserving a scholarship to ranking the cities of the world according to their liveability, involves the evaluation of several alternatives with respect to different aspects, technically called *evaluation criteria*. Multiple Criteria Decision Aiding (MCDA) (see [1, 2]) provides methodologies to recommend the Decision Maker (DM) a decision that best fits the DM's preferences. Formally, in MCDA, a set of n alternatives $A = \{a_1, \dots, a_n\}$ is evaluated with respect to a consistent family of m criteria $G = \{g_1, \dots, g_m\}$ [3]. In general, each criterion $g_j \in G$ can be considered as a real-valued function $g_j : A \rightarrow$

$\mathcal{I}_j \subseteq \mathbb{R}$, where the elements of $\mathcal{I}_j$ are real numbers having either the meaning of quantities for quantitative criteria or the meaning of ordered identifiers for qualitative criteria, for example, 1 = "bad", 2 = "medium", 3 = "good". Each criterion g_j can have an increasing or a decreasing direction of preference. In the first case, the higher the evaluation $g_j(a)$, the better a is with respect to criterion g_j ; in the other case, the higher the evaluation $g_j(a)$, the worse a is with respect to criterion g_j . For example, evaluating a car involves both quantitative and qualitative criteria having increasing or decreasing direction of preference. Price and acceleration are typical quantitative criteria, whereas comfort and safety are qualitative criteria. Among these, acceleration, comfort and safety have an increasing direction of preference, whereas price has a decreasing direction of preference. In the following, without loss of generality, we shall suppose that criteria have increasing direction of preference.

According to Roy [4], in MCDA, the following three most important decision problems are considered:

- the *choice* problem, requiring to select a small number (as small as possible) of "good" alternatives in such a way that a single alternative may finally be chosen;
- the *sorting* problem, requiring to assign each alternative to some predefined and ordered categories;
- the *ranking* problem, requiring to define a complete or partial order on A ; this preorder is the result of a procedure allowing to put together in classes alternatives that can be judged indifferent and to rank these classes.

Given two alternatives $a, b \in A$ and considering their evaluations on the m criteria belonging to family G , very often a will be better than b for some of the criteria, whereas b will be better than a for the remaining criteria. For this reason, in order to cope with the three above-mentioned problems, it

is necessary to aggregate the evaluations of the alternatives, considering the preferences of the DM. In the literature, the three best known ways of aggregation are the following:

- assigning to each alternative $a \in A$ a real number synthesizing the evaluations of a on the m criteria and being representative of the desirability of a with respect to the problem at hand, as it is the case in MAUT—multiattribute utility theory [5, 6],
- building some outranking preference relation S on A , such that for any $a, b \in A$, aSb means that a is at least as good as b , as it is the case in outranking methods [3, 7, 8],
- using a set of “if..., then...” decision rules induced from the DM’s preference information through dominance-based rough set approach (DRSA, see Refs 9–12).

The above-mentioned three ways of aggregation lead to three models of DM’s preferences, called shortly *preference models*. They have been compared at an axiomatic level with respect to their capacity of representation. The comparison leads to a conclusion that the decision rule model is the most general and able to represent the most complex interactions among criteria [13, 14].

In the case of the first model, in order to assign a real number to each alternative, we consider a value function $U : \prod_{j=1}^m \mathcal{I}_j \rightarrow \mathbb{R}$, such that for any $a, b \in A$, a is at least as good as b ($a \succeq b$) if $U(g_1(a), \dots, g_m(a)) \geq U(g_1(b), \dots, g_m(b))$. The simplest form of the value function is the additive form, defined as $U(g_1(a), \dots, g_m(a)) = \sum_{j=1}^m u_j(g_j(a))$, where $u_j(g_j(a))$ are nondecreasing functions of their arguments. In the following, for simplicity of notation, we shall use $U(a)$ instead of $U(g_1(a), \dots, g_m(a))$ for all $a \in A$.

In the case of the second model, we consider a function $S : \prod_{j=1}^m \mathcal{I}_j \times \prod_{j=1}^m \mathcal{I}_j \rightarrow \mathbb{R}$, non-decreasing in its first m arguments and nonincreasing in its last m arguments, such that for each $a, b \in A$, we have

- $S((g_1(a), \dots, g_m(a)), (g_1(b), \dots, g_m(b))) = 1$ if aSb , and $S((g_1(a), \dots, g_m(a)),$

$(g_1(b), \dots, g_m(b))) = 0$ otherwise, in case a crisp outranking relation is considered,

- a outranks b with a credibility $S((g_1(a), \dots, g_m(a)), (g_1(b), \dots, g_m(b))) \in [0, 1]$ in case a fuzzy outranking relation is considered.

In the case of the third model, starting from some preference information provided by the DM in the form of decision examples, the aim is to express relationships between the comprehensive decision concerning an alternative and its evaluations on relevant criteria, using “if..., then...” decision rules, such as

- “if maximum speed of a car is at least 175 km/h, and its price is at most 12,000 euro, then this car is comprehensively at least medium.”

The choice of a multicriteria decision-aiding method well adapted to the decision context depends on several aspects of the decision process and the cooperation between the analyst and the DM [15].

ORDINAL REGRESSION

Each decision model requires specification of some parameters. For example, using MAUT, the parameters are related to the formulation of the marginal value functions $u_j(g_j(a))$, $j = 1, \dots, m$. Eliciting direct preference information from the DM can be counterproductive in real-world decision-making situations because of a high cognitive effort required. Consequently, within MCDA, many methods have been proposed to determine the parameters characterizing the considered decision model in an indirect way, that is, inducing the values of such parameters from some holistic preference comparisons of alternatives given by the DM. This indirect preference elicitation is less demanding of cognitive effort and it is mainly used in the ordinal regression paradigm.

The most well-known ordinal regression methodology is the UTA (UTilités Additives) method proposed by Jacquet-Lagrèze and

Siskos [16], which aims at inferring one or more additive value functions from a given complete ranking on a reference set of alternatives A^R . The method considers a piecewise additive value function $U(a) = \sum_{j=1}^m u_j(g_j(a))$ having marginal value functions $u_j(\cdot), j = 1, \dots, m$, being piecewise

$$\begin{aligned} \max \quad & \varepsilon, \text{ s.t.} \\ & U(a^*) \geq U(b^*) + \varepsilon \quad \text{if } a^* \succ b^*, \text{ with } a^*, b^* \in A^R, \\ & U(a^*) = U(b^*) \quad \text{if } a^* \sim b^*, \text{ with } a^*, b^* \in A^R, \\ & \sum_{j=1}^m u_j(\beta_j) = 1, \quad u_j(\alpha_j) = 0, \quad j = 1, \dots, m, \\ & u_j(g_j(a)) \geq u_j(g_j(b)) \quad \text{if } g_j(a) \geq g_j(b), \forall a, b \in A, j = 1, \dots, m, \end{aligned} \quad \left. \begin{array}{l} \\ \\ \\ \end{array} \right\} \begin{array}{l} E^A \\ \\ E \end{array}$$

where

- β_j and α_j are the best and the worst considered values of criterion $g_j, j = 1, \dots, m$,
- $\succ$ and $\sim$ are the asymmetric and the symmetric part of the binary relation $\succsim$, representing the DM's preference information, that is, $a^* \succsim b^*$ means that a^* is at least as good as b^* for the DM,
- here, as always in the following, ε is considered without any constraint on the sign.

If the set of constraints E^A is feasible and $\varepsilon^* > 0$, then there exists at least one additive value function compatible with the DM's preferences. If there is no compatible value function, that is, if the preferences of the DM cannot be represented by an additive value function with pre-defined number of linear pieces, [16] suggests either to increase the number of linear pieces in some marginal value functions or to select the utility function U that gets the sum of deviation errors close to minimum and minimizes the number of ranking errors in the sense of Kendall or Spearman distance.

The ordinal regression paradigm has been applied within the two main MCDA approaches: those using a value function as preference model [16–20], and those using an outranking relation as preference model [21, 22].

linear, with a predefined number of linear pieces. UTA uses linear programming to assess the additive value function compatible with the preference information provided by the DM. Technically, we have to solve a linear programming problem of the type:

ROBUST ORDINAL REGRESSION

Usually, from among many sets of parameters of a preference model representing the preference information given by the DM, only one specific set is selected and used to work out a recommendation.

As the selection of one from among many sets of parameters compatible with the preference information given by the DM is rather arbitrary, *Robust Ordinal Regression* (ROR) proposes taking into account all the sets of parameters compatible with the preference information, in order to give a recommendation in terms of necessary and possible consequences of applying all the compatible preference models on the considered set of alternatives: the *necessary* weak preference relation holds for any two alternatives $a, b \in A$ ($a \succsim^N b$) if and only if a is at least as good as b for all compatible preference models, whereas the *possible* weak preference relation holds for this pair ($a \succsim^P b$) if and only if a is at least as good as b for at least one compatible preference model.

Although UTA^{GMS} [23] is the first method applying the ROR concepts, in the following, we shall describe the GRIP method [24] being its generalization taking into account intensity of preference. Then, we shall mention the other applications of the ROR that have been published later in several papers.

GRIP

In the UTA^{GMS} method [23], which initiated the stream of further developments in ROR,

the ranking of reference alternatives does not need to be complete as in the original UTA method [16]. Instead, the DM may provide pairwise comparisons just for those reference alternatives, he or she really wants to compare. Precisely, the DM is expected to provide a partial preorder $\succsim$ on A^R .

Obviously, one may also refer to the relations of strict preference $>$ or indifference $\sim$, which are defined as, respectively, the asymmetric and symmetric part of $\succsim$. The transition from a reference preorder to a value function is done in the following way: for $a^*, b^* \in A^R$,

$$\left. \begin{aligned} U(a^*) &\geq U(b^*) + \varepsilon, \text{ if } a^* > b^*, \\ U(a^*) &= U(b^*), \text{ if } a^* \sim b^*, \end{aligned} \right\} E_1$$

where ε is a (generally small) positive value.

In some decision-making situations, the DMs are willing to provide more information than a partial preorder on a set of reference alternatives, such as “ a^* is preferred to b^* at least as much as c^* is preferred to d^* .” The information related to the intensity of preference is accounted by the GRIP method [24]. It

$$\left. \begin{aligned} U(a^*) - U(b^*) &\geq U(c^*) - U(d^*) + \varepsilon, \text{ if } (a^*, b^*) > (c^*, d^*), \\ U(a^*) - U(b^*) &= U(c^*) - U(d^*), \text{ if } (a^*, b^*) \sim (c^*, d^*), \\ u_j(a^*) - u_j(b^*) &\geq u_j(c^*) - u_j(d^*) + \varepsilon, \text{ if } (a^*, b^*) \succ_j (c^*, d^*) \text{ for } g_j \in G, \\ u_j(a^*) - u_j(b^*) &= u_j(c^*) - u_j(d^*), \text{ if } (a^*, b^*) \sim_j (c^*, d^*) \text{ for } g_j \in G. \end{aligned} \right\} E_2$$

In order to check if there exists at least one model compatible with the preferences of the DM, we solve the following linear programming problem:

$$\begin{aligned} \varepsilon^* &= \max \varepsilon, \text{ s.t.} \\ E \cup E_1 \cup E_2 &= E^{\text{DM}} \end{aligned}$$

If the set of constraints E^{DM} is feasible and $\varepsilon^* > 0$, then there exists at least one additive value function compatible with the preference information provided by the DM, otherwise no additive value function is compatible with the provided information. In this case, the analyst can decide to check for the

may refer to the comprehensive comparison of pairs of reference alternatives on all criteria or to a particular criterion only. Precisely, in the holistic case, the DM may provide a partial preorder $\succsim^*$ on $A^R \times A^R$, whose meaning is: for $a^*, b^*, c^*, d^* \in A^R$,

$$(a^*, b^*) \succsim^* (c^*, d^*) \iff a^* \text{ is preferred to } b^* \text{ at least as much as } c^* \text{ is preferred to } d^*.$$

When referring to a particular criterion $g_j \in G$, rather than to all criteria jointly, the meaning of the expected partial preorder $\succsim_j^*$ on $A^R \times A^R$ is the following: for $a^*, b^*, c^*, d^* \in A^R$,

$$(a^*, b^*) \succsim_j^* (c^*, d^*) \iff a^* \text{ is preferred to } b^* \text{ at least as much as } c^* \text{ is preferred to } d^* \text{ on criterion } g_j.$$

In both cases, the DM is allowed to refer to the strict preference and indifference relations rather than to weak preference only. The transition from the partial preorder expressing intensity of preference to a value function is the following: for $a^*, b^*, c^*, d^* \in A^R$,

cause of the incompatibility [25] or can continue the decision-aiding process accepting the incompatibility.

Denoting by $\mathcal{U}_{AR}$ the set of value functions compatible with the preference information provided by the DM, in the GRIP method, three types of possible and necessary preference relations can be defined:

- $a \succsim^N b$ iff $U(a) \geq U(b)$ for all $U \in \mathcal{U}_{AR}$, with $a, b \in A$,
- $a \succsim^P b$ iff $U(a) \geq U(b)$ for at least one $U \in \mathcal{U}_{AR}$, with $a, b \in A$,
- $(a, b) \succsim^{*N} (c, d)$ iff $U(a) - U(b) \geq U(c) - U(d)$ for all $U \in \mathcal{U}_{AR}$, with $a, b, c, d \in A$,

- $(a, b) \succsim^{*P}(c, d)$ iff $U(a) - U(b) \geq U(c) - U(d)$ for at least one $U \in \mathcal{U}_{AR}$, with $a, b \in A$,
- $(a, b) \succsim_j^{*N}(c, d)$ iff $u_j(a) - u_j(b) \geq u_j(c) - u_j(d)$ for all $U \in \mathcal{U}_{AR}$, with $a, b, c, d \in A$, $g_j \in G$,

- $(a, b) \succsim_j^{*P}(c, d)$ iff $u_j(a) - u_j(b) \geq u_j(c) - u_j(d)$ for at least one $U \in \mathcal{U}_{AR}$, with $a, b \in A$, $g_j \in G$.

Given alternatives $a, b, c, d \in A$, and the sets of constraints

$$\begin{aligned}
 & \left. \begin{array}{l} U(b) \geq U(a) + \varepsilon \\ E^{\text{DM}} \end{array} \right\} E^N(a, b), & \left. \begin{array}{l} U(a) \geq U(b) \\ E^{\text{DM}} \end{array} \right\} E^P(a, b) \\
 & \left. \begin{array}{l} U(c) - U(d) \geq U(a) - U(b) + \varepsilon \\ E^{\text{DM}} \end{array} \right\} E^N(a, b, c, d), & \left. \begin{array}{l} U(a) - U(b) \geq U(c) - U(d) \\ E^{\text{DM}} \end{array} \right\} E^P(a, b, c, d) \\
 & \left. \begin{array}{l} u_j(c) - u_j(d) \geq u_j(a) - u_j(b) + \varepsilon \\ E^{\text{DM}} \end{array} \right\} E_j^N(a, b, c, d), & \left. \begin{array}{l} u_j(a) - u_j(b) \geq u_j(c) - u_j(d) \\ E^{\text{DM}} \end{array} \right\} E_j^P(a, b, c, d)
 \end{aligned}$$

we get that:

- $a \succsim^N b$ iff $E^N(a, b)$ is infeasible or it is feasible and $\varepsilon^N(a, b) \leq 0$, where $\varepsilon^N(a, b) = \max \varepsilon$, s.t. $E^N(a, b)$;
- $a \succsim^P b$ iff $E^P(a, b)$ is feasible and $\varepsilon^P(a, b) > 0$, where $\varepsilon^P(a, b) = \max \varepsilon$, s.t. $E^P(a, b)$;
- $(a, b) \succsim^{*N}(c, d)$ iff $E^N(a, b, c, d)$ is infeasible or it is feasible and $\varepsilon^N(a, b, c, d) \leq 0$, where $\varepsilon^N(a, b, c, d) = \max \varepsilon$, s.t. $E^N(a, b, c, d)$;
- $(a, b) \succsim^{*P}(c, d)$ iff $E^P(a, b, c, d)$ is feasible and $\varepsilon^P(a, b, c, d) > 0$, where $\varepsilon^P(a, b, c, d) = \max \varepsilon$, s.t. $E^P(a, b, c, d)$;
- $(a, b) \succsim_j^{*N}(c, d)$ iff $E_j^N(a, b, c, d)$ is infeasible or it is feasible and $\varepsilon_j^N(a, b, c, d) \leq 0$, where $\varepsilon_j^N(a, b, c, d) = \max \varepsilon$, s.t. $E_j^N(a, b, c, d)$;
- $(a, b) \succsim_j^{*P}(c, d)$ iff $E_j^P(a, b, c, d)$ is feasible and $\varepsilon_j^P(a, b, c, d) > 0$, where $\varepsilon_j^P(a, b, c, d) = \max \varepsilon$, s.t. $E_j^P(a, b, c, d)$;

As to properties of $\succsim^N$ and $\succsim^P$ on A , let us remind after [23] that

- $\succsim^N$ is a partial preorder on A ,
- $\succsim^N \subseteq \succsim^P$,
- $a \succsim^N b$ and $b \succsim^P c \Rightarrow a \succsim^P c$, $\forall a, b, c \in A$,

- $a \succsim^P b$ and $b \succsim^N c \Rightarrow a \succsim^P c$, $\forall a, b, c \in A$,
- $a \succsim^N b$ or $b \succsim^P a$, $\forall a, b \in A$.

The above-mentioned properties are the minimal ones characterizing $\succsim^N$ and $\succsim^P$ [26]. Other interesting properties of $\succsim^N$ and $\succsim^P$ are the following [23]:

- $\succsim^P$ is strongly complete and negatively transitive,
- $\succ^P$ is complete, irreflexive, and transitive.

FURTHER DEVELOPMENTS

When looking at the final ranking, the DM is mainly interested in the position that is attained by a given alternative and, possibly, in its comprehensive score. Therefore, in the RUTA method [27], the kind of preference information that may be supplied by the DM have been extended by information referring to the desired rank of reference alternatives, that is, final positions and/or scores of these alternatives. Indeed, people are used to refer to the desired ranks of the alternatives in their judgments. In many real-world decision situations (e.g., evaluation of candidates for a certain position), they use statements such as a^* should be among the 5% of best/worst alternatives or b^* should be ranked in the

second ten of alternatives. These statements refer to the range of allowed ranks that a particular alternative should attain. When using such expressions, people do not confront “one vs” as in pairwise comparisons or “pair vs” as in statements concerning intensity of preference, but rather rate a given alternative individually, comparing it with all the remaining alternatives jointly. Extreme ranking analysis [28] provides the worst and the best positions that each alternative can obtain considering the whole set $\mathcal{U}_{AR}$ of compatible value functions. See Refs 29–31 for some recent applications of the extreme ranking analysis methodology.

A great majority of methods designed to support the multiple criteria decision process, assuming that all evaluation criteria are considered at the same level. However, practical applications are often imposing a hierarchical structure of criteria. For example, in economic ranking, alternatives may be evaluated on indicators that aggregate evaluations on several subindicators, and these subindicators may aggregate another set of subindicators, etc. In this case, the marginal value functions may refer to all levels of the hierarchy, representing the values of particular scores of the alternatives on indicators, subindicators, sub-sub-indicators, etc. In multiple criteria hierarchy process (MCHP)[32–34], the DM may provide a partial preorder of reference alternatives in each node of the hierarchy and obtain a necessary and a possible preference relation on the whole set of alternatives in each node. MCHP permits to decompose a complex decision problem into a series of simpler subproblems.

UTADIS^{GMS} method [35] applies the ROR to sorting problems. The DM can provide preference information in terms of assignment of alternatives to intervals of classes obtaining as result, for each alternative, intervals of classes to which it can be assigned necessarily and possibly considering the whole set of compatible value functions. This approach has been subsequently extended to the DIS-CARD method, which additionally admits specification of desired class cardinalities [36].

ROR has been applied to extend the two best known families of outranking methods, which are ELECTRE [37] and PROMETHEE [28], giving birth to the ELECTRE^{GKMS} and the PROMETHEE^{GKS} methods. In these methods, the DM can provide preference information in terms of outranking of an alternative over another and/or can give comparisons among weights, possible intervals of weights, and intervals of thresholds. As a result, ROR gives necessary and possible outranking relations between alternatives considering the whole family of sets of preference model parameters (weights, indifference, preference and veto thresholds, and concordance cutting level) compatible with preference information.

Even if the additive model is among the most popular ones, some critics have been addressed to this model because it has to obey an often unrealistic hypothesis about preferential independence among criteria. In consequence, it is not able to represent *interactions* among criteria [38]. For example, consider evaluation of cars using such criteria as maximum speed, acceleration, and price. In this case, there may exist a negative interaction (*redundancy*) between maximum speed and acceleration because a car with a high maximum speed also has a good acceleration, so, even if each of these two criteria is very important for a DM who likes sport cars, their joint impact on reinforcement of preference of a more speedy and better accelerating car over a less speedy and worse accelerating car will be smaller than a simple addition of the two impacts corresponding to each of the two criteria considered separately in validation of this preference relation. In the same decision problem, there may exist a positive interaction (*synergy*) between maximum speed and price because a car with a high maximum speed usually also has a high price, and thus a car with a high maximum speed and relatively low price is very much appreciated. Thus, the comprehensive impact of these two criteria on the strength of preference of a more speedy and cheaper car over a less speedy and more expensive car is greater than the impact of the two criteria considered separately in validation of this preference relation.

To handle the interactions among criteria, one can consider *non-additive integrals*, such as Choquet integral and Sugeno integral (see, e.g., Ref. 39). ROR has been applied to such types of preference models originating the *NonAdditive Robust Ordinal Regression* (NAROR) [40]. However, the non-additive integrals suffer from limitations within MCDA [41]; in particular, they need that the evaluations on all criteria are expressed on the same scale. This means that in order to apply a nonadditive integral it is necessary, for example, to estimate if the maximum speed of 200 km/h is as valuable as the price of €35,000. Thus, in order to consider positive and negative synergies, UTA^{GMS} method has been extended to the UTA^{GMS}-INT method [42], which considers a value function, composed not only of the sum of marginal nondecreasing value functions but also of penalty and bonus functions representing negative and positive synergies between criteria, respectively. On the basis of a value function similar to that one used in UTA^{GMS}-INT, the customer satisfaction method MUSA^{INT} [43] applies the ROR concept to compare different customer profiles considering all the value functions compatible with the customers' preferences.

ROR has also been adapted to aid a group of DMs, $\mathcal{D} = \{d_1, \dots, d_p\}$, to cooperate in view of taking a collective decision. In UTA^{GMS}-GROUP and UTADIS^{GMS}-GROUP methods [44], the collective results account for the preferences expressed by each DM. For example, based on the necessary ($\succsim_{d_r}^N$) and possible ($\succsim_{d_r}^P$) preference relations for each DM d_r , in the UTA^{GMS}-GROUP method, four relations can be defined:

- $a \succsim_{\mathcal{D}}^{N,N} b : a \succsim_{d_r}^N b \text{ for all } d_r \in \mathcal{D},$
- $a \succsim_{\mathcal{D}}^{N,P} b : a \succsim_{d_r}^N b \text{ for at least one } d_r \in \mathcal{D},$
- $a \succsim_{\mathcal{D}}^{P,N} b : a \succsim_{d_r}^P b \text{ for all } d_r \in \mathcal{D},$
- $a \succsim_{\mathcal{D}}^{P,P} b : a \succsim_{d_r}^P b \text{ for at least one } d_r \in \mathcal{D}.$

Considering results of four different types permits to indicate what would happen always (for all compatible functions), sometimes (for at least one compatible function), or never (for none of the compatible

functions) with respect to a subset or to the whole set of DMs. In this way, one can investigate spaces of consensus and disagreement between the DMs.

Even if the recommendations obtained using ROR are “more robust” than a recommendation made using an arbitrarily chosen compatible model, in some decision-making situations, a score is needed to be known for different alternatives; for this reason, some users would like to see the “representative” model among all the compatible ones. The motto underlying this proposal is “one for all, all for one.” The representative value function represents all compatible value functions, which also do contribute to its definition. On the basis of the ROR concept, the representative model is the compatible model maximizing the difference of values between alternatives a and b for which a is necessarily preferred to b but b is not necessarily preferred to a and minimizing the difference of values between alternatives a and b for which neither a is necessarily preferred to b nor b is necessarily preferred to a . The representative model concept has been introduced for the first time in Ref. 45 and then applied to deal with ranking and choice problems [46, 47], outranking methods [48], sorting problems [49], and group decision making [50].

In order to explain the necessary and possible preference relations given by ROR in terms of conditions on evaluation criteria, [51] proposes to couple ROR with DRSA [52]. Applying DRSA to the necessary and possible preference supplied by ROR, we get decision rules stating, for example, that the preference, either necessary or possible, of alternative a over alternative b is explained by a strong preference on criterion g_{j_1} and at least mild preference on criterion g_{j_2} . In this case, the strong preference on criterion g_{j_1} and the at least mild preference on criterion g_{j_2} become the arguments suggested by the rule for the preference of a over b . In a learning perspective, decision rules supplied by DRSA can be the starting point for an interactive procedure for analyzing and constructing the DM's preferences. It enables the DM's understanding of the conditions for the

suggested recommendation and provides useful information about the role of particular criteria or their subsets.

ROR has been applied in multiple objective optimization (MOO; for an exhaustive collection of surveys on MOO, see Ref. 53) in Refs 54 and 55. In the first paper, GRIP method is used for an interactive exploration of the Pareto optimal set of a MOO. In the latter paper, pairwise comparisons provided by the DM are used to systematically contract a cone formed by the directions of the isoquants of all compatible achievement scalarizing functions. This cone is focusing the DM's attention on a subregion of the non-dominated set that better corresponds to his or her preferences.

It is also worth mentioning that ROR has been applied to guide evolutionary multiobjective optimization (EMO), that is, a procedure that approximates the Pareto front of a multiobjective optimization problem evolving an initial population of solutions through multiple generation by breeding and mutation, toward the set of solutions most preferred by the DM [56, 57].

Recent extensions of the ROR approach are presented in Refs 58 and 59 where the Stochastic multiobjective acceptability analysis (SMAA) [60] and the ROR are put together under a unified decision support framework.

CONCLUSION

In this article, we have presented the ROR being a family of multicriteria decision-aiding methods aiming at considering not only one compatible preference model but also the whole set of models compatible with some preference information provided by the DM in terms of pairwise comparison of some alternatives, intensities of preference, rank-related requirements, or statements concerning interaction between criteria. We have presented the GRIP method being the extension of the first ROR method UTA^{GMS} . We have also mentioned other applications of the ROR, including hierarchy of criteria (MCHP), sorting problems ($UTADIS^{GMS}$), outranking methods ($ELECTRE^{GKMS}$ and $PROMETHEE^{GKS}$), non-additive integrals

(NAROR), group decisions (UTA^{GMS} -GROUP and $UTADIS^{GMS}$ -GROUP), and MOO.

ROBUST PORTFOLIO SELECTION

DESSISLAVA
A. PACHAMANOVA
Associate Professor of
Operations Research,
Babson College, Wellesley,
Massachusetts

In the practice of finance, *robust portfolio selection* refers to the allocation of assets in such a way that the resulting portfolio is less sensitive to errors in the predicted behavior of the assets. Most generally, there are two stages to the quantitative robust portfolio selection process. At the *forecasting stage*, tools from robust statistics are utilized for the estimation of various parameters that are inputs to portfolio optimization models. At the portfolio *allocation stage*, simulation, robust optimization, and certain types of stochastic programming methods are used to minimize the effect of errors made at the forecasting stage. In the operations research literature, the term *robust portfolio selection* is used to refer mostly to the allocation stage. Hence, while some background for the most widely used robust forecasting techniques will be provided, the focus of this entry will be on robust portfolio optimization.

In order to place robust portfolio selection methods in context, the first section provides a brief summary of classical asset allocation models. The following sections discuss forecasting, simulation, and optimization methods used to make the classical models more robust or to improve their theoretical and computational characteristics.

ASSET ALLOCATION MODELS

The classical mean-variance portfolio allocation problem, first formulated by Markowitz [1], has the form

$$\begin{array}{ll}\max_{\mathbf{w}} & \mu' \mathbf{w} - \lambda \mathbf{w}' \Sigma \mathbf{w} \\ \text{s.t.} & \mathbf{w}' \mathbf{e} = 1\end{array}$$

where μ is the vector of expected returns (alphas) for N assets in the investment universe, Σ is the asset–asset covariance matrix, $\mathbf{w}$ is the N -dimensional vector of portfolio weights, λ is the risk aversion coefficient, and $\mathbf{e}$ is a vector of ones. This optimization problem formulation states that the optimal portfolio weights should be chosen so that the expected portfolio return less the portfolio risk (where risk is defined as the portfolio variance), scaled by the risk aversion coefficient, is as large as possible. The equality constraint ensures that the portfolio weights add up to one.

The above-mentioned portfolio optimization formulation is written in a utility maximization form. (The investor utility function corresponding to mean-variance optimization is the quadratic utility function.) The utility maximization framework is a parallel theory to the framework of mean-risk portfolio selection, and has its roots in the economic literature (e.g., [2]). Two alternative formulations used to describe the mean-variance portfolio allocation framework are (i) to minimize the portfolio variance subject to a constraint on the portfolio expected return and (ii) to maximize the portfolio expected return subject to a constraint on the portfolio variance. Solving these optimization problems for a range of values of the expected return (in the case of portfolio variance minimization) or the portfolio variance (in the case of expected return maximization) allows one to trace the efficient frontier of a portfolio; that is, to find the portfolios that dominate all other portfolios for any given level of expected return or risk.

The mean-variance portfolio optimization problem is a special case of the general mean-risk portfolio allocation framework, in which a portfolio risk measure is minimized subject to a constraint on the expected portfolio return. Advanced measures of risk include value-at-risk or VaR [3,4], conditional value-at-risk or CVaR [5], and lower partial moments [6,7], among others.

In their classical form, portfolio optimization problems are not robust with respect to small changes in their inputs, such as

expected returns or covariance matrices. As documented in multiple studies [8–13], a small change in the input parameters in the mean-variance optimization formulation can result in large swings in the optimal portfolio allocation. The effect is particularly strong in the case of errors in the estimation of the expected returns. In the mean-variance framework, the relative importance depends on the investor’s risk aversion, but as a general rule of thumb, errors in the expected returns are about 10 times more important than errors in the covariance matrix, and errors in the variances are about twice as important as errors in the covariances [14].

ROBUST PARAMETER ESTIMATION

Inputs to portfolio optimization models need to be estimated from data. In classical statistics, this is done by using maximum likelihood estimators (MLEs). For example, the sample mean and the sample covariance matrix are the MLEs for the true mean and covariance matrix when the underlying distribution is normal. When the sample distribution deviates even slightly from the assumed underlying distribution, however, the efficiency of these classical estimators may be drastically reduced. One approach to rectify the issues with unstable estimates is to use robust estimators. Examples of robust estimators are the median (in place of the sample mean) and the mean absolute deviation (MAD) (in place of the sample standard deviation). Advanced robust estimators include M- and S-estimators. Robust estimators may not be as efficient as MLEs when the underlying model is correct, but their properties are not as sensitive to deviations from the assumed distribution.

Robust estimation techniques for minimum-risk portfolios are discussed, for example, in [15–18]. These articles compute robust estimates of the covariance matrix of asset returns and solve a minimum-variance portfolio optimization problem, in which the covariance matrix is replaced by its robust estimate. Lauprete *et al.* [19] as well as DeMiguel and Nogales [20] study

portfolios for which robust parameter estimation and portfolio optimization are done in a single step.

Another issue is that inputs to portfolio optimization problems are often estimated from *historical* data. This can lead to counterintuitive, unstable, or merely “wrong” portfolios. Bayesian and shrinkage estimators are widely used for combining historical estimates with investor sentiments. (For a review of such estimators, see, e.g., Chapters 6 and 8 in Fabozzi *et al.* [21] and Chapter 9 in Pachamanova and Fabozzi [22].)

Bayesian estimation approaches are based on subjective interpretations of the probability that a particular event will occur. A probability distribution, called the *prior distribution*, is used to represent the investor’s knowledge about the probability before any data are observed. After more information is gathered (e.g., data are observed), Bayes’ rule is used to compute the new probability distribution, called the *posterior distribution*.

In the portfolio parameter estimation context, a posterior distribution of expected returns is derived by combining the forecast from the empirical data with a prior distribution. One of the most well-known examples of the application of the Bayesian framework in this context is the Black–Litterman model [23], which produces an estimate of future expected returns by combining the market equilibrium returns (i.e., returns that are derived from pricing models and observable data) with the investor’s subjective views. The investor’s views are expressed as absolute or relative deviations from the equilibrium together with confidence levels of the views (as measured by the standard deviation of the views).

Shrinkage is a form of averaging different estimators. The shrinkage estimator typically consists of three components: (i) an estimator with little or no structure (such as the sample mean); (ii) an estimator with a lot of structure (the shrinkage target); and (iii) a coefficient that reflects the shrinkage intensity. Probably the most well-known estimator for expected returns in the financial literature was proposed by Jorion [24]. The shrinkage target in Jorion’s model is a

vector array with the return on the minimum variance portfolio from the Markowitz portfolio optimization model, and the shrinkage intensity is determined from a specific formula. Shrinkage estimators are used for estimates of the covariance matrix of returns as well [25], although equally weighted portfolios of covariance matrix estimators have been shown to be as effective as shrinkage estimators [26].

Regardless of how sophisticated the estimation and forecasting methods are, there is always estimation error. With advances in computational capabilities and new research in the area of optimization under uncertainty, practitioners in recent years have been able to incorporate considerations for uncertainty not only at the estimation, but also at the portfolio optimization stage. Methods for considering inaccuracies in the inputs to the portfolio optimization problem include simulation (resampling) and robust optimization. The next two sections explain these robust portfolio selection techniques.

PORTFOLIO RESAMPLING

Portfolio resampling involves generating different scenarios for the values of the input parameters in a portfolio optimization problem by simulation, and finding weights that remain stable for small changes in those parameters [27–29]. An illustration of the resampling technique as applied to portfolio mean-variance optimization is as follows.

Given an initial vector of expected stock returns, $\hat{\mu}$, and covariance matrix, $\hat{\Sigma}$, for the N stocks in the portfolio, it is estimated based on T observations of the vector of asset returns:

1. Simulate S samples of size T either from a multivariate normal distribution with mean $\hat{\mu}$ and covariance matrix $\hat{\Sigma}$ or by sampling with replacement from the empirical data set;
2. Use the S samples from step 1 to compute S new estimates of vectors of expected returns $\hat{\mu}_1, \dots, \hat{\mu}_S$ and covariance matrices $\hat{\Sigma}_1, \dots, \hat{\Sigma}_S$;

3. Solve S portfolio optimization problems, one for each estimated pair of expected returns and covariances $(\hat{\mu}_s, \hat{\Sigma}_s)$ and save the weights for the N assets in a vector array $\mathbf{w}^{(s)}$, where $s = 1, \dots, S$;
4. To find robust portfolio weights, average out the weight for each asset over the S weights found for that asset in each of the S optimization problems.

The probability distribution for the portfolio weights obtained from the portfolio resampling process is a valuable piece of information. By plotting the weights for each asset obtained over the S iterations, one can get a sense for how variable this stock weight is in the portfolio.

A disadvantage to calculating robust portfolio weights by averaging the results of a simulation *after* the optimization stage, however, is that the final weights may not actually satisfy some of the constraints in the optimization formulation. In general, only convex constraints are guaranteed to be satisfied by the averaged final weights. Turnover constraints, for example, may not be satisfied. This fact, combined with the fact that the procedure is time-consuming and computationally intensive, can be serious limitations of the resampling approach for practical applications.

ROBUST PORTFOLIO OPTIMIZATION

Robust optimization incorporates uncertainty directly into the portfolio optimization process, and can be used in conjunction with robust portfolio estimation methods. The robust optimization paradigm (e.g., [30]) is to deal with uncertainty in optimization model inputs by requiring that the optimal solution to the optimization problem remains feasible for any realization of the uncertain parameters within prespecified uncertainty sets. Robust optimization can therefore be viewed as a max-min (or a min-max) approach depending on the structure of the constraints in the optimization problem because the constraints need to be satisfied for the worst-case values of the uncertain

parameters within the uncertainty sets. (The max-min/min-max interpretation for the robust optimization approach is similar in the case of uncertainty in the parameters of the objective function in an optimization problem—one optimizes the worst-case objective function value as the uncertain parameters vary in their prespecified uncertainty sets.)

The uncertainty sets themselves may contain infinitely many elements; however, by suitable reformulation of the problem for special kinds of uncertainty sets, a computationally tractable *robust counterpart* of the original optimization problem can be obtained that sometimes can also be linked to probabilistic guarantees on the feasibility of the optimal solution.

Robust Formulations of Classical Portfolio Allocation Frameworks

Early work in robust portfolio optimization focused on modeling uncertainty sets for inputs to the classical mean-variance problem. As an example, consider a confidence interval around each expected return forecast, which results in a “box” uncertainty set for the expected returns in the mean-variance portfolio optimization formulation,

$$U_\delta(\hat{\mu}) = \left\{ \mu \mid |\mu_i - \hat{\mu}_i| \leq \delta_i, i = 1, \dots, N \right\}.$$

The robust formulation of the portfolio selection problem is

$$\begin{aligned} \max_{\mathbf{w}} \quad & \min_{\mu \in U_\delta(\hat{\mu})} \{ \mu' \mathbf{w} \} - \lambda \mathbf{w}' \Sigma \mathbf{w} \\ \text{s.t.} \quad & \mathbf{w}' \mathbf{e} = 1 \end{aligned}$$

and it can be shown (e.g., [31] or [22]) that the robust counterpart of the problem under this uncertainty set is equivalent to

$$\begin{aligned} \max_{\mathbf{w}} \quad & \mathbf{w}' \mu - \delta' |\mathbf{w}| - \lambda \cdot \mathbf{w}' \Sigma \mathbf{w} \\ \text{s.t.} \quad & \mathbf{w}' \mathbf{e} = 1 \end{aligned}$$

where $|\mathbf{w}|$ denotes the vector of component-wise absolute values of the entries of the vector of weights $\mathbf{w}$. Note that if the weight of

stock i in the portfolio is negative, the worst-case expected return for stock i is $\mu_i + \delta_i$ (the investor loses the largest amount possible). If the weight of stock i in the portfolio is positive, the worst-case expected return for stock i is $\mu_i - \delta_i$ (the investor gains the smallest amount possible). Observe that $\mu_i w_i - \delta_i |w_i|$ equals $(\mu_i - \delta_i)w_i$ if the weight w_i is positive and $(\mu_i + \delta_i)w_i$ if the weight w_i is negative. Hence, the robust counterpart minimizes the worst-case expected portfolio return. Stocks whose mean return estimates are less accurate (i.e., have a larger estimation error δ_i) are penalized in the objective function, and tend to have a smaller weight in the optimal portfolio allocation.

The effect of this particular “robustification” of the mean-variance portfolio optimization formulation can be viewed in two different ways. On the one hand, the values of the expected returns for the different stocks are adjusted downwards in the objective function of the optimization problem. In other words, the robust optimization model “shrinks” the expected return of stocks with large estimation error, that is, in this case the robust formulation is related to the shrinkage methods discussed earlier. On the other hand, the additional term in the objective function can be interpreted as a “risk-like” term that represents penalty for estimation error. The size of the penalty is determined by the investor’s aversion to estimation risk, and is reflected in the magnitude of the deltas.

Consider now an ellipsoidal uncertainty set for the expected return estimates,

$$U_\delta(\hat{\mu}) = \{ \mu \mid (\mu - \hat{\mu})' \Sigma_\mu^{-1} (\mu - \hat{\mu}) \leq \delta^2 \},$$

where Σ_μ is the covariance matrix of estimation errors for the vector of expected returns μ . This uncertainty set captures the idea of a joint confidence region, and represents the requirement that the scaled sum of squares (scaled by the inverse of the covariance matrix of estimation errors) between all elements in the set and the point estimates $\hat{\mu}_1, \hat{\mu}_2, \dots, \hat{\mu}_N$ can be no larger than δ^2 . In practical applications, the covariance matrix of estimation errors is often assumed to be diagonal. In the latter case, the set contains all vectors of expected returns that

are within a certain number of standard deviations from the point estimate of the vector of expected returns, and the resulting robust portfolio optimization problem would protect the investor if the vector of expected returns is within that range.

The robust counterpart of the mean-variance portfolio optimization problem with an ellipsoidal uncertainty set for the expected return estimates is the following optimization problem formulation:

$$\begin{aligned} \max_{\mathbf{w}} \quad & \mathbf{w}'\boldsymbol{\mu} - \lambda \cdot \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} - \delta\sqrt{\mathbf{w}'\boldsymbol{\Sigma}_\mu\mathbf{w}} \\ \text{s.t.} \quad & \mathbf{w}'\mathbf{e} = 1. \end{aligned}$$

This is a second-order cone problem, which is computationally tractable and has a similar interpretation to the robust counterpart in the case of the box uncertainty set. Garlappi *et al.* [31] provide an interpretation of this robust model in terms of optimizing over a set of multiple priors as advocated by Gilboa and Schmeidler [32], thus pointing out links between the robust optimization approach, Bayesian estimators for expected returns, and decision theory.

A practical issue when applying the above-mentioned robust optimization model is as follows. This simple robust portfolio optimization model, which is also the one most widely considered in practice, assumes that the mean returns of the assets lie within an uncertainty set that reflects the estimation errors, whereas the covariances are known. If S independent historical asset returns are available, each of which is assumed to follow the same distribution with known covariance matrix, then, by the central limit theorem, the most natural uncertainty set for the unknown vector of expected returns is the ellipsoidal uncertainty set presented earlier in this section. As shown earlier, the robust portfolio optimization model based on this uncertainty set yields a portfolio optimization framework analogous to the classical one by Markowitz [1]. The reason for this is that the error covariance matrix for the mean returns is proportional to the covariance matrix of the returns themselves. This does not eliminate the problem observed in practice when

applying the classical Markowitz framework, which is that Markowitz portfolios are highly sensitive to small changes in input parameters (expected returns and covariance matrices).

Non-Markowitz portfolios can only be obtained if the error covariance matrix is no longer proportional to the covariance matrix of returns. One possible remedy is the zero-net α adjustment proposed by Ceria and Stubbs [33], in which the ellipsoidal set for the expected returns is intersected with a plane. On an intuitive level, the result is that the net adjustment in the total expected portfolio return can be controlled (as opposed to the case of the simple robust optimization formulation, in which the net adjustment in the expected portfolio return is always downwards). The structured uncertainty set proposed by Ceria and Stubbs [33] changes the characteristics of the optimal portfolios and also reduces the conservativeness of the optimal portfolio allocations that are often observed when using robust portfolio optimization in practice.

A variety of different uncertainty sets have been considered in the literature. Lobo and Boyd [34] consider not only interval uncertainty sets for the expected returns vector, but also the element-wise interval uncertainty sets for the covariance matrix. They show that the corresponding robust counterpart is a semi-definite programming problem. Tütüncü and Koenig [35] also consider box uncertainty sets for the expected returns and the covariance matrix. They show that the robust counterpart is a saddle-point problem, which can be solved efficiently. Costa and Paiva [36] consider uncertainty sets for the expected returns and the covariance matrices that are polytopes with known vertices and formulate the robust counterpart of a portfolio optimization model of the mean-variance type (minimum volatility of tracking error) over linear matrix inequalities. Goldfarb and Iyengar [37] show how uncertainty sets for the expected returns and covariance matrices can be mapped statistically to factor models for estimation of expected returns that are widely used in the financial industry and derive the robust counterparts of a number of portfolio optimization problems in the

factor model framework, including Sharpe ratio maximization and VaR minimization. Erdogan *et al.* [38] extend the latter approach to robust index tracking. Robust min-max portfolio selection over a set of competing scenarios is discussed in [39].

Outside the mean-variance portfolio optimization framework, Pinar and Tütüncü [40] use robust portfolio optimization in the context of finding minimum risk robust profit opportunities. Pachamanova [41] evaluates the performance of a robust formulation of the sample CVaR (using the d -norm uncertainty sets introduced by Bertsimas *et al.* [42]) for a portfolio of simulated and US market data. Quaranta and Zaffaroni [43] present a similar model, based on “box” uncertainty sets for the expected returns, and study its performance in the Italian market. Kawas and Thiele [44] introduce a single-period log-robust portfolio optimization approach, in which uncertainty sets are considered for the continuously compounded rates of return.

A comprehensive overview of the early work on robust portfolio optimization models is provided by Fabozzi *et al.* [21], and a more recent review of applications of robust optimization models in practice can be found in [45].

Distributional Uncertainty

In more recent developments, research in robust portfolio optimization has focused less on robust estimation of the parameters in classical portfolio allocation models from finance and more on finding the best allocation given some limited information about the distributions of the underlying uncertainties (asset returns), which can be, but is not limited to, first and the second moments. This research in robust optimization complements work on more general models of uncertainty that have a long history and span different areas, such as stochastic programming, economics, and finance ([46–49], among others). The uncertainty in the probabilistic model is often referred to as *ambiguity*.

El Ghaoui *et al.* [50] propose a framework for optimization of worst-case portfolio VaR based on information about first and second moments of the distribution of asset returns.

The minimum portfolio VaR problem is in fact an optimization problem with a chance constraint, and has the form

$$\begin{aligned} \min_{\gamma_0, \mathbf{w}} \quad & \gamma_0 \\ \text{s.t.} \quad & P(V_0 - \tilde{\mathbf{r}}'\mathbf{w} > \gamma_0) \leq \varepsilon \\ & \mathbf{w}'\mathbf{e} = 1 \end{aligned}$$

where V_0 is the value of the portfolio today and $\tilde{\mathbf{r}}$ is the vector of (uncertain) future asset returns. $V_0 - \tilde{\mathbf{r}}'\mathbf{w}$ is the change in portfolio value between today and a predetermined date in the future. In words, the portfolio VaR problem is to find the minimum value γ_0 so that the probability that the future portfolio loss exceeds γ_0 is less than or equal to a small constant ε (typically $\varepsilon = 5$ or 1%). If we introduce a new variable $\gamma = \gamma_0 - V_0$, the VaR optimization problem can be reformulated as

$$\begin{aligned} \min_{\gamma, \mathbf{w}} \quad & \gamma + V_0 \\ \text{s.t.} \quad & P(\gamma + \tilde{\mathbf{r}}'\mathbf{w} \geq 0) \geq 1 - \varepsilon \\ & \mathbf{w}'\mathbf{e} = 1. \end{aligned}$$

Using a multidimensional version of the Chebyshev inequality, El Ghaoui *et al.* [50] show that the robust counterpart of the VaR portfolio optimization problem (i.e., the optimization formulation for the worst-case portfolio VaR over all possible probability distributions with a given vector of means and covariance matrix) is a second-order cone problem of the kind

$$\begin{aligned} \min_{\gamma, \mathbf{w}} \quad & \gamma + V_0 \\ \text{s.t.} \quad & -E[\tilde{\mathbf{r}}'\mathbf{w}] + \alpha\sqrt{\mathbf{w}'\Sigma\mathbf{w}} \leq \gamma \\ & \mathbf{w}'\mathbf{e} = 1 \end{aligned}$$

where $E[\cdot]$ denotes expectation and α is a constant related to ε . Note that this formulation is reminiscent of the mean-variance portfolio optimization framework.

Natarajan *et al.* [51] generalize the model of El Ghaoui *et al.* to take advantage of information about asymmetry in the underlying probability distributions. They study the worst-case portfolio, that is, the VaR portfolio

optimization problem, given the information about the mean returns and the forward and backward deviations of factors that drive asset returns. (See [52] for a definition of forward and backward deviations.)

Zhu and Fukushima [53] derive the worst-case CVaR portfolio optimization formulation for special cases of probability distributions, such as a box uncertainty set and a mixture distribution of some possible distribution scenarios. Huang *et al.* [54] consider a related problem of portfolio selection under distributional uncertainty in a relative robust CVaR approach, where relative CVaR is related to the worst-case risk of the portfolio relative to a benchmark. Natarajan *et al.* [55] derive the worst-case CVaR portfolio optimization problem for all distributions of uncertain returns with given moment information.

Mean-variance and mean-absolute deviation portfolio allocation problems under distributional uncertainty are studied by Calafiore [56], who derives the worst-case portfolio allocation if the true probability distribution of the uncertain returns is assumed to lie within a distance d from an estimated nominal distribution, with distance measured according to the Kullback–Leibler divergence measure.

Popescu [57] introduces the idea of worst-case portfolio allocation with expected utility maximization given partial information about the distribution of uncertain returns. She considers the single-period robust (maximin) expected utility problem

$$\max_{\mathbf{w}} \min_{\tilde{\mathbf{r}}} E[u(\tilde{\mathbf{r}}' \mathbf{w})]$$

under the assumption that the first and the second moments of the uncertain returns are known exactly. The author suggests a parametric quadratic programming algorithm for solving the problem that is efficient for a large class of utility functions. The idea is further developed by Delage and Ye [58], who propose an approach that works for a smaller family of utility functions but considers moment uncertainty, and by Natarajan *et al.* [59], who assume that the supports and the first two moments of distributions of the random returns are known and also address the issue of moment uncertainty. Chen *et al.* [60]

maximize the expected utility or minimize the disutility over infinitely many possible ambiguous distributions of the investment returns fitting a given mean and variance estimates. In the case of a single-stage portfolio optimization problem, they show that when the disutility function is in the form of lower partial moments, VaR or CVaR, the problem can be solved analytically. They also consider the so-called S-shaped utility function that plays a key role in the prospect theory of Kahneman and Tversky [61] and show an efficient procedure for solving the robust counterpart of the corresponding portfolio selection problem.

Wozabal [62] introduces a framework for dealing with ambiguity of the distribution of random asset losses in the portfolio selection problem. He defines “robustified” risk measure versions of several portfolio risk measures, including the standard deviation, the CVaR, and the general class of distortion functionals that measure the worst-case portfolio risk over an ambiguity set of loss distributions, where an ambiguity set is defined as a neighborhood around a reference probability measure representing an investor’s beliefs about the distribution of asset losses. A numerical study shows that in most instances the robustified risk measures perform significantly better out-of-sample than their non-robust variants in terms of risk, expected losses, and turnover.

Zymler *et al.* [63] deal with the problem of portfolio optimization under distributional uncertainty in the presence of assets with nonlinear payoffs such as European options. They develop two tractable conservative approximations for the VaR of a derivative portfolio by evaluating the worst-case VaR over all return distributions of the derivative underlies with given first- and second-order moments.

A connection between weak and strong robustnesses guarantees and portfolio insurance is discussed in [64]. The authors propose a model for designing portfolios that trades off weak and strong guarantees on the worst-case portfolio return. The weak guarantee applies as long as the asset returns are realized within the prescribed uncertainty set,

while the strong guarantee applies for all possible asset returns.

Robust Optimization and Risk Measures

Consider the following portfolio selection problem, in which asset returns are assumed to be uncertain parameters:

$$\begin{aligned} \max_{\mathbf{w}} \quad & \min_{\tilde{\mathbf{r}} \in U_\lambda(\tilde{\mathbf{r}})} \{\tilde{\mathbf{r}}' \mathbf{w}\} \\ \text{s.t.} \quad & \mathbf{w}' \mathbf{e} = 1. \end{aligned}$$

where the uncertainty set for the asset returns is defined using the expected returns $\boldsymbol{\mu}$ and the covariance matrix of returns $\boldsymbol{\Sigma}$ as

$$U_\lambda(\tilde{\mathbf{r}}) = \{\mathbf{r} \mid (\mathbf{r} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{r} - \boldsymbol{\mu}) \leq \lambda^2\}.$$

As observed by Ben-Tal and Nemirovski [65], the above-mentioned problem is equivalent to the classical mean-standard deviation portfolio allocation problem in finance,

$$\begin{aligned} \max_{\mathbf{w}} \quad & \boldsymbol{\mu}' \mathbf{w} - \lambda \sqrt{\mathbf{w}' \boldsymbol{\Sigma} \mathbf{w}} \\ \text{s.t.} \quad & \mathbf{w}' \mathbf{e} = 1. \end{aligned}$$

This perspective has led to interesting findings about the relationship between robust portfolio selection and decision theory, and has provided economic meaning to the selection of uncertainty sets in robust optimization.

The correspondence between the shape of uncertainty sets in robust optimization and some popular portfolio risk measures is explored in more detail by Natarajan *et al.* [55]. One of the most applicable aspects of this work for finance practice is to use robust optimization to modify traditional risk measures from finance in a way that improves their theoretical properties. For example, the authors present guidelines for selecting the uncertainty set in such a way as to create coherent (in the sense of Artzner *et al.* [66]) versions of traditionally noncoherent risk measures such as VaR. Specifically, if the uncertainty set for the returns is specified so that it is a subset of the convex hull of the actual set of possible values of the uncertainties in the portfolio optimization problem, then the risk

measure defined by that uncertainty set is coherent.

These results are related to a duality result that can be traced back to the robust statistics literature [67]. There is now a large body of literature on the relationship between coherent risk measures and worst-case expected portfolio return over a family of probability distributions. The so-called *representation theorem* (e.g., [68]) states that a risk measure $\rho(\cdot)$ is coherent if and only if there exists a family of probability measures $\mathbb{Q}$ such that

$$\rho(\tilde{v}) = \sup_{Q \in \mathbb{Q}} E_Q[-\tilde{v}]$$

where $E_Q(\tilde{v})$ denotes the expectation of the random variable $\tilde{v}$ under the measure Q (as opposed to the measure of $\tilde{v}$ itself). In the portfolio optimization context, $\tilde{v}$ is the portfolio return. Bertsimas and Brown [69] examine the connections between risk management tools, distributional ambiguity, and robust optimization using this result as a starting point. Specifically, with risk preferences specified by a coherent risk measure, they examine the implications for uncertainty set structure in robust linear optimization problems.

The correspondence between uncertainty sets in robust optimization and risk measures in finance has been explored in interesting ways that go beyond typical portfolio optimization. For example, using results obtained by Natarajan *et al.* [55], Bertsimas *et al.* [70] derive a generalization of the Black–Litterman approach for estimating expected returns in traditional mean-variance optimization and illustrate how to construct “BL”-type estimators for more general notions of risk such as coherent risk measures. Computationally efficient multiperiod portfolio allocation models, discussed in the next section, also take advantage of this relationship.

Multiperiod Portfolio Optimization

Portfolio management is an inherently multiperiod problem. By incorporating long-term views on asset behavior, portfolio managers can take advantage of opportunities better

and can reduce their transaction costs, as the portfolio will not get rebalanced unnecessarily often. Gulpinar and Rustem [71] discuss robust multiperiod mean-variance optimization over a scenario tree, assuming ambiguity in the estimation of the mean and the covariance structure of unknown returns. Robust portfolio optimization over scenarios in a multiperiod setting is also studied by Pinar [72] who focuses on downside risk measures.

Multiperiod portfolio optimization schemes are generally difficult to handle computationally because the optimization problems are of large dimension. Robust optimization techniques with roots in the robust control literature, as well as adjustable robust optimization techniques, have been suggested to create a portfolio optimization formulation that can be more easily applied in practice.

Ben-Tal *et al.* [73] were the first to suggest a generalization of mean-standard deviation optimization for multiple time periods as a robust optimization problem that can be written as a second-order cone problem of small dimension, thus reducing substantially the computational difficulties in solving the portfolio allocation problem over multiple stages. They study the performance of their method versus stochastic programming methods for multistage portfolio management and find that the method is not only preferable in terms of computational tractability, but also in terms of realized portfolio performance according to a variety of measures. The main idea of Ben-Tal *et al.*'s approach is actually related to a technique for modeling dynamic programming problems, the certainty equivalent controller (CEC), that has been well known in engineering applications for many years. The CEC technique applied at stage t of a particular dynamic programming problem finds the optimal policy by assuming that all uncertain parameters for subsequent stages are fixed at their expected values; that is, it eliminates the uncertainty from the optimization problems. An obvious drawback of this approach is that risk is not considered in the solution to the problem. Ben-Tal *et al.* extend the CEC and incorporate risk by considering ellipsoidal uncertainty sets around the random parameters at all subsequent

time periods. (The random parameters in the case of the multiperiod portfolio optimization problem are the future asset returns.) Consequently, if there are T time periods, the multiperiod portfolio optimization formulation becomes a single optimization problem with T balance constraints that imitate solving single-period mean-standard deviation portfolio problems linked across time.

A subsequent study by Bertsimas and Pachamanova [74] explores other aspects of the robust optimization approach to multiperiod portfolio optimization, such as introducing different uncertainty sets to make the resulting optimization problem linear and comparing the approach to single-period mean-standard deviation optimization under variety of assumptions for the stochastic behavior of the asset returns. The general conclusion from computational studies is that incorporating views on the direction of asset prices in the future through multiperiod robust optimization models tends to reduce transaction costs and improve overall portfolio performance characteristics such as realized average return, median return, and probability of loss.

Adjustable robust optimization [75], an active research area in robust optimization, is a promising new framework for solving multiperiod portfolio optimization problems. It accommodates models, for example, in which information reveals itself gradually over time and decisions in the future can be made with knowledge of events that have happened until the current time period. However, problems defined as adjustable robust optimization problems can be severely computationally intractable, and so far applications have been limited to special cases. For example, Chen *et al.* [60] find a multistage adjustable robust optimization solution to the portfolio optimization problem when an investor has a disutility function that is the second-order lower partial moment.

ROBUSTNESS ANALYSIS

ROBUSTNESS IN HISTORICAL AND CONCEPTUAL CONTEXT

This entry deals with a specific sense of the term *robustness*, that was coined by Gupta and Rosenhead [1]. The word was borrowed from common usage: the meanings recorded in the Oxford Dictionary include “strong and hardy of body or constitution” and “strongly and stoutly built.” However, robustness has also been used and has currency in a number of other technical senses close enough in meaning to run the risk of generating confusion.

The most well-established previous use of the term is in the field of statistics, where it is used to denote a statistical estimator or procedure that is relatively insensitive to departure from the distributional assumptions made when calibrating it. Huber [2] attributes the first use of the word robustness in this sense to Box [3] in 1953.

Bayesians give the term a rather more specific meaning. A Bayesian application is robust if the posterior distribution for an unknown parameter is not unduly affected by the choice either of the prior distribution or of the form of model taken to be generating the data [4]. More recently the field of *robust optimization* [5] has become of research and practical interest. However, as will be seen, the concept of optimization sits uneasily with that of robustness in the sense of this entry.

A more nearly compatible use of the term *robustness* is due to Roy and his collaborators [6]. Somewhat analogously to sensitivity analysis, Roy's approach seeks to incorporate

the real-world experience of uncertainty into the understanding and interpretation of mathematically derived results. Sensitivity analysis is well known and widely used. It is a systematic procedure that can be used to explore how an optimal solution responds to changes in inputs—typically these are either predicted values which might vary in the future or parameters whose values are open to question. The analysis aims at discovering how sensitive the “optimal” solution is to changes in crucial factors.

Roy's sense of “robustness” differs from sensitivity analysis in two principal ways. The first is that it aims to handle not only optimization but a range of other computational results, for example, that a certain solution is feasible, or that it is near optimal. The second difference is that its perspective is virtually the mirror image of that of sensitivity analysis. Its thrust is, rather, to identify the domain of points in the solution space for which a particular result continues to hold.

However, Roy's robustness also differs in two ways from robustness analysis as described in this article. Uncertainty is attached to parameter values, rather than to the swathe of possibly intangible “unknown unknowns” [7] that are likely to be resistant to credible quantification. And as with sensitivity analysis, the idea of exploiting sequentiality to achieve flexibility is absent.

The “robustness” of robustness analysis is a measure of the degree of flexibility of future decision possibilities that an act of commitment makes or leaves available. A commitment is an action with consequences, to be implemented without unnecessary delay following the act of decision. These consequences make any commitment irreversible, in the sense that it would take a further decision with *its* associated consequences and costs to “reverse” it. A decision not to give effect to any of the possible actions under consideration is also a commitment.

Any commitment is taken as acting upon and changing an existing system, with the

intention of improving or maintaining its performance. The subsequent decisions, which will or may be taken at points in the future, will also have that aim, though in new circumstances.

“Robustness” is an alternative or supplementary criterion to that of unmediated performance. “Performance,” here, is used to signify the directly useful or harmful attributes or outputs of the system of interest. It may be taken as uni- or multi-dimensional, depending on the focus of the evaluation. Robustness, by contrast, is a metalevel concept derived from estimates of future performance in order to evaluate the extent of useful flexibility left for the interim system which would result from alternative initial commitments.

FLEXIBILITY

Flexibility becomes of interest in decision making when (i) the degree of uncertainty about the future behavior of the system, or about its future context, is sufficient to make the establishment of an optimal decision or decision path a dubious proposition; and (ii) there will be later opportunities or indeed requirements to take further decisions that have impacts on the system. If both of these conditions hold, then flexibility consists in having the ability to choose between a range of meaningful options at these future decision points. The greater the range of this choice, the greater the remaining flexibility. The freedom to make choices is perhaps the most basic of all the freedoms that people, whatever their position or role, can have. However this freedom is empty if decisions taken earlier, by you or some others, have deprived you of meaningful alternatives from which to choose.

Operational research/management science (OR/MS) has tended to downplay the decisional issues arising from uncertainty. The emphasis, rather, has been on optimization, which requires as its precondition a belief in the certainty of estimates of performance or at least in the reliability of the probability distribution of such estimates.

However, these conditions of certainty of outcome (or of probabilities of outcomes) are at best approximated, and then in only a subset of decision problems—usually those with a relatively limited forward time span. Among important issues debated in the public domain that fail or have failed these tests are climate change, financial regulation, international conflict resolution, crime prevention, and epidemic management. In some of these an approach based on valuing flexibility could in principle have (or have had) more traction. The more strategic problems of private enterprises, communities, or individuals also tend to be characterized by uncertainties for which even probabilistic estimation is problematic.

Although not widely known within OR/MS, a range of approaches to identify and characterize flexibility have been developed. These include [8]:

adaptability: the ability to accommodate successfully to a new environment;

versatility: the possession of the necessary capabilities and the ability to apply them to the challenges of new circumstances that develop; and

resilience: the ability to withstand shocks without permanent damage and to rebound or recoil.

What distinguishes robustness analysis from these approaches is (i) it incorporates the MS/OR orientation toward choice between alternatives; and (ii) it provides an operational definition of flexibility, namely, *robustness*.

ROBUSTNESS ANALYSIS

The definition of the robustness of an initial commitment is

the number of acceptable options at the planning horizon that are compatible with that commitment, as a ratio of the total number of acceptable options.

The logic underlying this definition is illustrated in Fig. 1.

Figure 1. Schematic for robustness definition. d_i , a possible commitment; $\circ$, an unacceptable option; $\bullet$, an acceptable option; $\bullet$, an acceptable option compatible with d_i .

In slightly more formal notation, if S is the set of all options at the planning horizon with acceptable performance, S_i is the subset of S that is compatible with initial commitment d_i , and $n(\cdot)$ denotes cardinality or the number of elements in a set, then the robustness of commitment d_i is given by

$$r(d_i) = n(S_i)/n(S).$$

If none of the acceptable options are compatible with the selection of a particular commitment, its robustness score will be zero. If all the acceptable options are still available, its robustness score is 1. Thus, all robustness scores lie in the range $[0, 1]$. Higher scores are preferred to lower ones.

Robustness is an attribute of the initial commitment, and not of any plan (the options at the planning horizon). These plans are hypothetical constructs that are used to form judgments between alternative commitments. Robustness analysis can thus be seen as bifocal—one lens to focus on the next step, the other to survey the longer-term possibilities. However, the relationship between these two views is the reverse of that in conventional analytic approaches to planning, in which the immediate commitment is seen as a first step to the achievement of the identified long-term solution. In robustness analysis, rather, the longer-term is employed as a means to inform current decisions.

It is not suggested that decision makers should automatically select and implement the commitment that has the highest robustness score. There are factors other than flexibility to consider—cost, short-term benefits,

and so on. The balance between these elements will depend on circumstances. The advantage that robustness analysis brings to decision making is a language in which flexibility can participate systematically in the conversation.

Among the applications of robustness analysis are

- brewery locations across the United States [1];
- chemical plant expansion in the Dead Sea, Israel [9];
- strategic planning for hospital development for an Australian new town [10]; regional health planning for Ottawa-Carleton, Canada [11]; and
- sequential development of food production by a poor Brazilian community [12].

To employ robustness analysis it is necessary to

- identify the initial commitments to be evaluated;
- select a planning horizon (typically 5–10 years, depending on the speed of change in the environment and the time lag in implementing decisions);
- clarify the range and variety of future options that could result at the planning horizon;
- establish which commitments are compatible with, that is, leaving available, which options; and
- determine the acceptability of future options.

These steps provide the necessary elements for calculating the robustness scores for candidate initial commitments.

There is an irreducible element of judgment in preparing a problem for robustness analysis. In particular, “acceptability” may be based on quantitative information derived from a model plus an agreed threshold; or it may be based on judgments made by those who will be responsible for operating the system. “Compatibility” will sometimes be of a logical nature—if a particular commitment is not made, then certain avenues forward, which depend upon it, become inaccessible. Or the argument may be more nuanced—along the lines of “is or is not commitment C a reasonable first step if we were to think of option O as our destination?”

Where compatibility is based on logic, it will often be possible to build a graph showing the retention and attenuation of options through a series of future decision stages. In other cases, it will not be possible to identify the set of options at the planning horizon as simply consisting of the feasible combinations of intermediate decisions, so that no staged graphical representation will be possible. A method for generating options and establishing compatibility links between options and commitments in such cases is given in Rosenhead [13, pp. 198–200].

The judgments involved in a robustness analysis formulation may be made by the analyst/consultant. More commonly there will be a need for inputs from the client organization. It may be advantageous to elicit these in a workshop format, so that the inputs have the benefit of discussion among the client group. Used in this participative mode, robustness analysis is a member of the family of problem structuring methods (see Rosenhead and Mingers [14], where a fuller account of robustness analysis is also given).

Where judgmentally based inputs have an arbitrary element or potentially contested nature, the issue can often be resolved by running the analysis with alternative versions, in effect a form of sensitivity analysis. If similar patterns of robustness scores then

emerge, commitment choices based on the analysis will be reinforced; if not, attention should be focused on the sensitive aspects of the problem formulation.

VARIANTS

Multiple Future Robustness

The account of robustness analysis given above has assumed that an option is definitively acceptable or unacceptable. However, in some cases the acceptability of options is expected to depend on exogenous events that may or may not occur. In this case it may be useful to conduct a multiple future robustness analysis. This requires the identification of a (usually small) number of Futures $\{F_j\}$. The acceptability of the performance of any option (and possibly its compatibility with some commitments) could now depend on which future is considered. The robustness of any commitment d_i within Future F_j can now be calculated as

$$r(d_{ij}) = n(S_{ij})/n(S_j)$$

where all terms are defined analogously to the single future case. Any commitment now has a set of robustness scores, one for each future. Analysis of the robustness of alternative commitments can often progress by the elimination of commitments through dominance.

Debility

The rationale of measuring robustness is to keep open desirable options. The same basic logic can be used where there is a particular concern to *avoid* access to future options that are assessed as likely to perform unacceptably. However, the logic now is reversed. We can define the *debility* of an initial commitment as

the number of *unacceptable* options at the planning horizon that are compatible with that commitment, as a ratio of the total number of unacceptable options.

As with robustness, debility is constrained by its definition to lie in $[0, 1]$. However, in a mirror image of robustness, it is low debility scores that are advantageous. (See Caplin and Kornbluth [9] for more details on debility.) It is possible to conduct a combined robustness and debility analysis, providing two flexibility related measures for each commitment for any given future. This can, in principle, provide an enriched web of information for discussion about how to manage decision making under uncertainty.

Robustness and Long-Term Policy Analysis

A distinctive application of the concept of robustness has been developed by the RAND Corporation [15]. The focus of this application is on “long-term policy analysis,” which is concerned with the identification, assessment, and choice among near-term actions that will shape the options available to future generations, 30 or more years ahead. This choice will need to be made under conditions of “deep uncertainty,” where those charged with decision making do not know the relationships that will shape the long-term future, cannot rely on probability distributions of the key variables and parameters, and have no reliable way of valuing the desirability of alternative options.

RAND’s method operates through the generation of potentially very large numbers of plausible futures (i.e., scenarios), which are then employed using special-purpose software to identify near-term strategies that are robust, that is, perform reasonably well across a wide range of scenarios.

ROBUSTNESS FOR OPERATIONS RESEARCH AND DECISION AIDING

BERNARD ROY
LAMSADE, Paris-Dauphine
University, Paris, France

WHAT IS OR-DA?

During World War II, the Allied Forces called upon several scientists (mainly mathematicians) to enlighten the strategic and tactical decisions in the theaters of operations. This was called *operations research* (OR) (operational research at the time). After the war, the scientists transposed what they had done in the battlefield to the corporate world, thus explaining the development of linear programming, the theory of games, the queuing theory, and more. By the late 1940s, in England, the United States, and later in France, consulting firms had the term OR in their corporate name. Aside from its purely mathematical component, OR is closely linked to decision aiding (DA), as can be clearly seen in the name [*Société Française de Recherche Opérationnelle et Aide à la Décision*, French Society for Operations Research and Decision Aiding] of the association whose purpose is to bring together researchers and practitioners in the field.

The men and women in business or the media who use the term *DA* are not necessarily referring to a scientific activity. Conversely, when talking about DA, operations research and decision aiding (OR-DA) necessarily adopts a scientific approach to the issues involving decision-making. The following definition is commonly accepted and often quoted:

Decision Aiding is the activity of the man or women who, relying on clearly explicit, but not necessarily formalized models, helps a stakeholder to reach the elements of answers to the questions that he or she may ask during a decision-making process. The elements should contribute to enlightening the decision,

communicating about the decision, drafting recommendations, or promoting behavior that would increase the coherence between the development of the decision-making process on the one hand, and the goals and value systems that the stakeholder is serving, on the other (Refs 1 and 2).

However, I cannot provide a definition for OR because there is no widely accepted definition of the terms. The first definition was “*operations research is what the Operations Research Company of New Jersey does*” (for more details, readers may refer to Refs 3 and 4).

Several fields of applications of OR-DA, among others, can be found below:

- assignment scheduling in a workshop or on a construction site;
- organizing delivery or pick-up rounds;
- drafting service schedules or timetables in a transport company;
- dam water management;
- the assignment of agricultural plots of land to classes of risk;
- the assignment of cancer cells to types of pathologies;
- routing communications within a telephone network;
- designing integrated circuits; and more.

Usefully, the reader's attention should be drawn to the following points. A person commonly called an *analyst* who practices DA relies on working hypotheses and models to reach *results* based on scientific foundations. The results may have various outcomes: satisfactory or optimal solutions, compromise proposals, acknowledgment of incoherence or incompatibility, the statements of conclusions, or even recommendations. Importantly, one should always keep in mind that the purpose of DA is not to dictate the “right decision” to the decision maker. DA does not claim to uncover hidden truths. DA must be designed in such a way to mesh with the decision-making process, thus enabling it to

evolve in accordance with the goals of the different stakeholders and facilitate mutual communication.

TWO CONCRETE EXAMPLES

Determination of the Characteristics of a Water Supply Network in an Urban Development Zone

I had to deal with this problem at a time when robustness in OR-DA was not yet an issue. I was then the scientific director of SEMA (Metra International). René Loué, an engineer at the Road and Bridges Authority, asked me what I thought of how the Roads and Bridges engineers were using an OR model to determine the structure and main characteristics of a water supply network for an urban development zone. The purpose of the very sophisticated model was to help define the optimal network that would meet a clearly defined demand for water, at the lowest cost, year after year over 30 years, in each neighborhood of the zone. On the basis of the land use plan scheduled for each neighborhood and the forecasts of household and business water consumption, the engineers had calculated the most probable volume of water that the network would have to supply, year after year, in each neighborhood.

According to René Loué, the land use plans were likely to change. How much the demand for water might change was also imperfectly known. Considering the imperfect knowledge and vague approximations in the modeling, René Loué felt that the optimum the Roads and Bridges engineers had found was totally misleading. If, several years later, actual demand sharply exceeded what they had determined as the most probable demand (to which the network had been finely adjusted) in certain areas, the streets would have to be torn up to change water lines, install new lines, and alter some other network features. On the other hand, if actual demand turned out to be much lower than the forecast probability, they would have made wasteful investments. Clearly, the best way of formulating the problem was not to search for the characteristics of a network that, for a given demand (considered as known: year

after year and neighborhood per neighborhood), would incur minimum investment and operational costs. The focus should rather be on gaining a grasp on what type of network would be the most likely to withstand a range of probable demands, considering the costs incurred by adjustments to actual demand. First, this meant that the approach could not be limited to a single scenario of the most probable demand, but had to introduce a range of plausible scenarios. Second, the model had to consider what it would cost to adjust the initially designed network to the scenario that would actually happen.

Choosing the Best Bid after a Call for Tenders

I will deal with this type of problem by referring to a concrete case where I helped find a solution, some 20 years ago. At the time, the French Post had decided to fit its regional mail-sorting centers with package sorting machines, which were still far from perfect. Therefore, it issued an international call for tenders for the construction of a prototype. The call for tenders had very detailed specifications and limited the cost of the mass-produced machine to a "specified objective cost." It received 15 bids.

Twelve criteria were used for the evaluation of each bid: prototype cost, stated deadline, the number of sorting directions, the number of sorted packages per hour, the rate of rejected or improperly sorted packages, sound levels, bag handling ease, occupied area, trust in the supplier to meet commitments, and three more technical criteria. Once each bid had been assessed by its 12 evaluation criteria, how should the best one be chosen? In this case, there was not one criterion to optimize. Considering the heterogeneity of the magnitudes serving for bid evaluation, designing a single criterion encompassing the 12 criteria was unrealistic. Regardless of the procedure selected to enlighten the choice, two aspects of the problem had to be considered:

1. Evaluating the bids on each criterion would inevitably comprise some uncertainty or arbitrariness.

2. The decision maker wanted some criteria to play a more important role than others.

I will deal later with each of the two aspects that are not specific to this particular problem.

WHAT IS ROBUSTNESS IN OR-DA?

As can be guessed by the two above examples, vague approximations and areas of ignorance, which affect modeling as well as what is commonly called the data, limit the scientific approach in OR-DA. Several examples of vague approximations and areas of ignorance can be found below:

- Modeling involves simplifying reality: several different ways are possible and only one is selected.
- One particular piece of information whose value is debatable is considered, as if it were certain.
- A random variable is supposed Gaussian, mainly for the purpose of facilitating calculations.
- Another source of vague approximations, which is often overlooked, involves the way of processing numbers, as if they represented a quantity: in the calculation, a deadline that is twice as long will be counted as being twice as penalizing, whereas it might actually be much more, or much less so.
- When modeling a system of (technical, economic, and social) constraints, one often overlooks the uppermost limit that is allowable within the (pressure, budget, and capacity) thresholds that mark (or will mark) the boundaries of the possible or the feasible in the future.
- When there are multiple criteria, the metaphor of weight is generally used to differentiate the role that the different criteria must play. However, often the weights do not refer to any objective reality, and the way they operate within the model is usually far from clear.

Importantly, the vague approximations and areas of ignorance (often referred to under the umbrella term *uncertainties*) have to be considered if useful answers are to be provided to the decision maker. Actually, not doing so may lead to misleading outcomes.

In OR-DA, *robust* is a qualifier that refers to an aptitude to withstand “vague approximations” or “areas of ignorance” to provide protection against deplorable impacts, such as results that are much worse than expected, or damage to properties to maintain (for more details see Refs 5–9).

The qualifier “robust” applies to various aspects, that is, solutions, conclusions, recommendations, and methods. Robustness primarily involves a *concern*. The concern must be present throughout DA, including at the time when the problem is formulated. This issue, which was raised at the end of the section titled “Determination of the Characteristics of a Water Supply Network in an Urban Development Zone,” is also highlighted in the following didactic example, which also underscores the share of subjectivity found in the concern for robustness.

Mrs. *D* is wavering between three solutions for her trip from *A* to *B*:

- *The subway*: This solution involves a change on the line. However, as the trains run regularly, she can estimate the travel time with a small margin of uncertainty.
- *A bus and a train*: The bus to the train station does not run very regularly. She also does not know the train timetable. However, the trains travel much faster than the subway does. Therefore, this solution is faster than the subway solution, but it might also take much longer if she has to wait for a bus and then for a train.
- *A car*: If there are no traffic jams, it is the fastest solution.

If the trip from *A* to *B* is a one-time event and if Mrs. *D* absolutely does not want to be late, she will find that the subway solution, albeit longer, is the most robust. If, on the other hand, it is a regular trip and if Mrs. *D*

considers that slight delays (as long as they do not occur too often) are acceptable, she might feel that, on average, subway travel time will be much longer than the travel time on the two other means of transportation. Therefore, the most robust solution has to be chosen from the two other solutions: even if traffic jams seldom occur, Mrs. *D* may fear that they would have unacceptable outcomes, something that would be less likely with the bus–train solution. In this case, the latter would seem to her as the most robust.

In the following paragraphs, I will call *the model on which DA relies and the procedures for processing the model to reach results*: formal representation (FR). I will call *the context, in which decisions will be made, executed, and judged*, a real-life context (RLC).

The decisions for which DA is performed will be implemented in a real-life situation that, undeniably, will not strictly conform to the model on which the DA relied. Furthermore, the decisions may be assessed in light of a value system, which may not necessarily be in perfect accordance with the system that was used to design and process the model. Therefore, seamless conformity between FR and RLC seems virtually impossible. This lack of conformity stems from extant vague approximations and areas of ignorance. The concern for robustness means that they have to be considered in the RF as best as possible; or the FR should consider at least those vague approximations or areas of ignorance that, if overlooked, would make DA unable to protect the decision maker from any deplorable impacts.

In a given decision-making situation, if the analyst is to meet the concern for robustness properly, he or she should design the FR while considering the two requirements that I will now explain.

TWO REQUIREMENTS TO MEET THE CONCERN FOR ROBUSTNESS PROPERLY

First requirement: Carefully inventory and properly consider all frailty points in the FR.

By definition, a *frailty point* is a place in the model, or in a procedure processing the model, where vague approximations or

areas of ignorance can be found. Considering a frailty point means retaining either a single option or a series of possible options. An *option* means a particular, precise way of dealing with vague approximations or areas of ignorance. For instance, an option may be:

- a given value assigned to imperfectly known data, or to a poorly defined parameter;
- a set of values setting the weight assigned to each of the relevant criteria;
- a particular probability distribution to characterize a random variable;
- a simplifying hypothesis making it possible to consider a complex phenomenon;
- a particular way of building a criterion to consider a point of view;
- a possible value assigned to a technical parameter involved in a processing procedure;
- the choice of a solution among the solutions closest to an optimum solution.

Given an identified frailty point, the analyst must ask himself or herself whether—by retaining only one option for the frailty point—he or she is running the risk that outcomes of model processing might conceal impacts that the decision maker may deem undesirable. If this is true, he or she should design a set of options likely to highlight the different eventualities. The set may be discrete (i.e., a few possible values, several sets of weights, two or three probability distributions, and two or three plausible hypotheses) or continuous (i.e., intervals of possible values and families of probability distributions characterized by parameters with values within the given intervals).

Second requirement: Design forms of answers likely to help the decision maker protect himself or herself from undesirable impacts that may result from vague approximations or areas of ignorance in the FR.

The forms of answers have to consider the decision maker's expectations of the said protection. Are there impact levels that he or she

is ready to accept in certain circumstances? Are there other levels that he or she considers unacceptable; levels for which he or she wants protection, whatever the circumstances or cost? Depending on the real-life context, and because of the vague approximations and areas of ignorance in the FR, the decision maker's decision could, to some extent, reconcile his or her need for protection on the one hand, with his or her desire to optimize the performance criterion or criteria serving to evaluate the solution, on the other. The forms of the analyst's answers will only be truly useful for the decision maker if enough information is provided, so that the latter can, in light of his or her own subjectivity, come to a decision. Given the two conflicting risks:

- Finding himself or herself poorly protected in the case of very poor performance revealing undesirable impacts.
- Finding himself or herself in a position whereby he or she forsakes any hope of good, or even very good performance.

The way both requirements are considered in current journals prompts me to make two observations, which I will present briefly (for more details, see Ref. 5).

First observation: The frailty points that are usually considered solely relate to the "data" whose purpose is to bring into play an aspect of RLC, which is called *uncertain*, into the FR.

This approach leads to design a set of *scenarios* to describe all the realities that are likely to happen and that must be considered by the concern for robustness. A scenario is defined by a single option chosen with regard to each frailty point within a set of related options. The set of scenarios may be finite or infinite.

Therefore, a proper formulation of the problem present in the section titled "Determination of the Characteristics of a Water Supply Network in an Urban Development Zone" means involving other narratives, alongside the narrative of the most probable water volumes (neighborhood per neighborhood), with each plausible narrative making up a scenario. This example also shows that

the relevant frailty points may also come from vague approximations and areas of ignorance, which are not necessarily related to the data on uncertain aspects of the RLC. Modeling water supply networks that will meet a given demand in the relevant zone involve various technical parameters. Several options for the value that will be assigned to each of the said parameters should be examined. The optimization criterion making it possible to process the model can also be formulated in different ways. Consequently, using the term *scenario* to describe a choice of options relating to the said frailty points may be inappropriate when communicating with the decision maker, who may assign a different meaning to the term. To ensure that all the frailty points are considered without restriction, I find it preferable to replace the concept of *scenario* with the concept of *version* (of the formulation of the problem). A version is still defined as a combination of options considering all the relevant frailty points (for more details, see Ref. 5). However, I will be using the term *scenario* in the rest of my article. Importantly, the frailty points that may be found in the way the model is processed should not be overlooked. This may lead to consider all the procedures in set P , wherein each p procedure is still defined by a precise option characterizing the procedure for each of the frailty points contained therein, rather than merely considering a single processing procedure.

Second observation: Most stakeholders are only interested in a single type of answer: find one (possibly several) solution(s) that can be qualified as "robust." To give the term meaning, they refer to an FR model where the performance of a solution is defined by a single criterion and they give preference to the performance of the solution in the worst-case scenario, to measure the robustness of the solution.

This type of answer relies on a fairly particular concept of a *robust solution* that fits within in a fairly restrictive schema that I will now address.

A FRAMEWORK SCHEMA TO MEET THE CONCERN FOR ROBUSTNESS

The schema may be defined by the three following characteristic traits.

Characteristic trait no. 1: In RF, the decisions, which have to be studied, are modeled as element a of a set A of the so-called feasible solutions. A single criterion g associates a performance $g(a)$ with each element. This criterion clears the way for defining the optimal solution or solutions, regardless of any concern for robustness.

Set A may be defined in *comprehension* by the set of solutions of a system of constraints, as can be seen in the example in the section titled “Determination of the Characteristics of a Water Supply Network in an Urban Development Zone.” In this example, criterion g is a cost criterion that has to be minimized. Set A can also be defined in *extension* by a list, as is the case in the example in the section titled “Choosing the Best Bid after a Call for Tenders.” However, in the latter example, it is not possible to characterize the performance of a bid by a single criterion to optimize.

Characteristic trait no. 2: A single measurement is defined to give meaning to the assertion “solution x is at least as robust as solution y .” This—and only this—measurement is involved when qualifying a solution as robust.

Three robustness measurements have been chiefly used since Kouvelis and Yu’s famous work [10]. I present them below in the event criterion g has to be minimized. On this subject, I will talk about cost (the cost being worth plus infinite for solution x , which is not feasible in scenario $s \in S$).

The first measurement relies on the notion of guaranteed cost. The guaranteed cost of solution x is the highest cost for the solution in the model. Therefore, it is the highest value of $g(x)$ in every scenario. Taking this guaranteed cost as the definition of the robustness measurement is the same as admitting that solution x is considered to be at least as robust as solution y , if, and only if, the guaranteed cost in x is, at most, equal to the cost guaranteed in y .

The two other robustness measurements rely on the concept of regret. One involves absolute regret and the other relative regret. Solution x having been selected, when the actual scenario is known, the decision maker may compare the $g(x)$ cost that he or she actually incurs in this scenario with the cost he or she would have incurred had the selected solution been the best in the scenario. Absolute regret is, by definition, the difference between the value of the $g(x)$ cost in the actual scenario and the cost incurred by the optimal solution in this scenario. Relative regret is defined by dividing absolute regret by the cost of solution x in the relevant scenario. Admittedly, the decision maker does not know which scenario will happen, but the maximum value for (absolute or relative) regret within all the scenarios clears the way for associating what can be called guaranteed regret with each solution x . Taking guaranteed regret as the definition of the robustness measurement is the same as admitting that solution x is considered at least as robust as solution y if, and only if, the guaranteed regret in x is, at most, equal to the guaranteed regret in y .

Characteristic trait no. 3: The single selected robustness measurement only involves the scenarios where it leads to the worst performance, or greatest regret, wherein what happens in the other scenarios does not play any role. Robust solutions are those that optimize the robustness measurement in every scenario.

Coguaranteed robustness measurements, guaranteed (absolute or relative) regret, involve considering only what happens in the most unfavorable scenarios (in terms of performance or regret), regardless of what happens in the other scenarios, to determine whether solution x deserves to be qualified as robust. This is a very particular way of addressing the concern for robustness. It cannot correspond to the decision maker’s picture of robustness. A solution thus qualified as robust may incur costs or cause regrets that are very mediocre in large number of scenarios. Basing the concern for robustness on the optimization of a cost or a guaranteed regret means admitting that one should primarily protect oneself as best

as possible against what might happen if the actual scenario is the worst (in terms of cost or regret) *vis-à-vis* the selected solution. This way of addressing the concern for robustness is not appropriate for the decision maker unless he or she has a very strong aversion to risk.

Characteristic trait no. 3 assigns a decisive role to the scenario (or scenarios) that determines the optimum of the robustness measurement in the definition of a robust solution (or solutions). The scenario (or scenarios) may be highly unlikely (for instance, corresponding to combinations of extreme options). Removing the scenario (or scenarios) from set S may lead to defining very different solutions as robust. This dependence of the solution qualified as robust on the presence of this or that scenario in S can be clearly seen in the case of the design of a water supply network (the section titled “Determination of the Characteristics of a Water Supply Network in an Urban Development Zone”), when all the scenarios were designed as was suggested in the section titled “Two Requirements to Meet the Concern for Robustness Properly” (see the end of the first observation).

OTHER WAYS OF DEFINING THE CONCEPT OF “ROBUST SOLUTIONS”

The above considerations explain why several authors have suggested definitions of “robust solutions” by avoiding characteristic trait no. 3 (Refs 5 and 11). I have suggested three new robustness measurements (*bw*-absolute robustness, *bw*-absolute deviation, and *bw*-relative deviation). Their purpose is to allow the decision maker to improve the way he or she would like to reconcile the two conflicting risks (see the end of the section titled “Two Requirements to Meet the Concern for Robustness Properly”). To do so, he or she must assign a value to two parameters, b and w ; b refers to a goal (in terms of cost or regret) that has to be reached or improved in the highest possible number of scenarios, whereas w sets the value of the worst cost or greatest regret that he or she would like to guarantee, regardless of which scenario actually happens ($w > b$). The decision maker who

agrees to assign a higher value to w than to w^* , guaranteed by solution x that optimizes the measurement of the related cost or guaranteed regret, obviously runs the risk that solution z (which is robust from the standpoint of the new selected measurement) may lead to a cost or regret higher than w^* , in a few scenarios. However, with solution z , the decision maker can trust that the costs or regrets will be better than what they would have been in solution x , in a very high number of scenarios (for more details, see Ref. 6).

Very few authors have attempted to define the robustness of a solution by involving several, rather than a single, robustness measurement (in other words, by avoiding characteristic trait no. 2). There are also very few authors who have attempted to address the concern for robustness, by avoiding characteristic trait no. 1. Readers may refer to the above-mentioned references for further details on both points.

Robustness can also be addressed by looking for types of answers that do not necessarily highlight solutions qualified as “robust.” Providing the decision maker with the so-called robust solutions is actually a very particular type of response, which does not always properly meet the second requirement (the section titled “Two Requirements to Meet the Concern for Robustness Properly”). I will now deal with a more general type of response.

THE CONCEPT OF “ROBUST CONCLUSIONS”

I will begin by introducing several notations. Let us take scenario $s \in S$ that has a perfectly defined model $M(s)$ in FR, the said model translating the way that the DA problem was formulated in the case where the real-life context corresponds to scenario s . In other words, $p \in P$ (the section titled “Two Requirements to Meet the Concern for Robustness Properly”) is a procedure considered for processing $M(s)$. The processing provides a set of outcomes $R(p, s)$ that may have various forms: optimal solution(s), uncontrolled solution(s), rejected solution(s), and the establishment of an impossibility or inconsistency. The analyst

relies on the said results to answer the decision maker's questions. For various reasons, the analyst may only focus on the outcomes involving pairs (p, s) that belong to a given subset Q of the Cartesian product $P \times S$.

By definition, here the term *conclusion* means an assertion that considers a certain set of outcomes of the $R(p, s)$ type. This kind of assertion is called a *robust conclusion* when it includes the statement of the conditions governing the establishment of its validity. The conditions involve the relevant subset Q of $P \times S$ and the conditions and hypotheses that give meaning to, and warrant the assertion. Therefore, the robustness of a conclusion is contingent on the field of validity defined by the said conditions.

The most commonplace statement of robust conclusions is the following, "solution x is robust, robust meaning that x is a solution that optimizes the measurement of robustness defined as follows (...) in all the outcomes $R(p, s)$ stemming from the relevant set Q ." Here, the selected robustness measurement and the relevant set Q define the field of validity of the robust conclusion.

There are less trivial forms of robust conclusions that do not refer to "robust solution." Several examples are given below.

"Except for the following procedures (...), all the $(p, s) \in Q$ pairs highlight the following evaluations (...) as feasible with the following evaluations (...)."

" $\forall (p, s) \in Q, x$ is a solution whose gap with the optimum solution never exceeds . . . %."

"There is no feasible solution that ensures that the following goals (...) (associated with different criteria) will be guaranteed, regardless of scenario $s \in S$."

"All the solutions $x_1, x_2, \dots, x_k$ have the following properties (...), except perhaps in some scenarios that are deemed as highly unlikely."

I will briefly summarize the role that the concept of "robust conclusions" has actually played in drafting recommendations in the example in the section titled "Choosing the Best Bid after a Call for Tenders," to highlight the practical contribution of "robust conclusions."

The set of feasible solutions was defined in extension by the 15 selected bids. Each

bid was evaluated on 12 criteria. Six of the solutions could be initially eliminated. Therefore, the FR model relied on what is called the *performance table*, which provides the performance for each of the nine solutions on each of the 12 criteria. To evaluate the performance on a concrete scale appropriate to each criterion, a group of experts of the French Post was set up. The frailty points related to the share of uncertainty or even arbitrariness, which might affect some of the evaluations, were inventoried. Basically, their impact could be considered by means of the concept of thresholds of indifference or preference, which do not have to be known to understand the rest of the example.

The selected processing procedure was ELECTRE IS. In this procedure, a set of weights characterizing the relative importance that the decision maker wanted to assign to each criterion had to be defined. For some of the criteria, a veto threshold could be introduced. In this case, the decision maker was a committee comprising several post office managers. The role that had to be assigned to each of the 12 criteria was not perceived in the same way by the technical manager, personnel manager, sales & marketing manager, or financial manager. Therefore, weights and vetoes were the frailty points in the way the model was processed.

To understand the meaning of the robust conclusions that were drawn, I do not have to go into the details of what set Q of the relevant (p, s) pairs covered. For each pair, the ELECTRE IS method highlighted a subset of solutions that seem the most satisfactory. The said subset had to be as small as possible, with the following constraint: any solution that was not in the subset could be eliminated, as it was not as good as at least one of the solutions in the subset. The said subset [that here play the role of the $R(p, s)$ outcome] corresponded to what is called a *kernel* in graph theory. Consequently, the method associated a kernel with each pair $(p, s) \in Q$.

A summarized version of the robust conclusions that were drawn on these bases can be found below.

Conclusion no. 1: Bid a_1 was found in almost all the kernels (this assertion was completed by the list of (p, s) pairs where a_1 was not in the matching kernel).

Conclusion no. 2: Bids a_5, a_6 , and a_8 could not be found in any kernel.

Conclusion no. 3: Bid a_9 could be found in some kernels; when this was the case, lowering the veto power of criterion 12 was enough to remove a_9 from the kernel (resulting in a_1 becoming as good as a_9).

Conclusion no. 4: The three bids a_2, a_3 , and a_4 formed a subset C of actions, which were indifferent in each pairwise comparison, which could be found in a large number of kernels.

Saying that bids a_2, a_3 , and a_4 were indifferent in each pairwise comparison meant that, with the available data at time, they could not be differentiated. Each bid of C could be considered as at least as good as each of the two others, without being substantially better.

Conclusion no. 5: Bid a_7 could be found in a large number of kernels; the actions of C were usually incomparable with a_7 .

Affirming this incomparability meant that, with the available data at the time, a_7 could not be considered as at least as good as any of the actions of C and that, vice versa, none of these actions could be considered as at least as good as a_7 .

These robust conclusions (completed by an appropriate analysis) led to the following recommendations that were submitted to the post general directorate (for more details, readers may refer to Ref. 12, Chapter 8).

1. In the case where no more than one prototype could be built, bid a_1 should be retained (conclusion no. 1).
2. In the case where more than one prototype could be built, bids a_5, a_6, a_8 , and a_9 should definitely be eliminated (conclusion nos. 2 and 3).
3. In the case where three prototypes could be built, bids a_1 and a_7 and one of the three bids of C should be retained (conclusion nos. 4 and 5). The 12 relevant criteria did not clearly differentiate bids a_2, a_3 , and a_4 (to do so, one could examine considerations that were not

(or poorly) considered by this family of criteria). If a_1 was actually retained, selecting a_3 at the same time would be more justified than selecting a_2 or a_4 because unlike the two latter, a_3 was usually incomparable with a_1 .

4. In the case where two prototypes could be built, it would be appropriate, in addition to a_1 , to chose either a_7 or one of the C bids, as a_7 was hard to compare with C bids, an option which basically brought the "decision maker's" value system into play.

CONCLUSION

To conclude, I would like to underscore two points.

1. In OR-DA, the notion of robustness has relatively tight connections with other notions such as flexibility, stability, reliability, adaptability, sensitivity, and sometimes even equity.
2. Meeting the concern for robustness supposes considering the eminently subjective way that the decision maker wants to protect himself or herself from catastrophic performance without having to forsake the hope for good, or even very good performance.

RULE DEVELOPING EXPERIMENTATION IN CONSUMER-DRIVEN PACKAGE DESIGN

ALEX GOFMAN
Moskowitz Jacobs Inc., White
Plains, New York
Marketing Department, Pace
University, Manhattan,
New York

The consumers make about 73% of their purchase decisions at the point of sale where more attractive packaging frequently leads to purchase [1]. Particularly, when the consumer is undecided, the package becomes a critical factor in the purchase choice because it communicates to consumers at the decision making time [2]. In this case, the package functions as a silent salesman [3,4], which some also call *the first moment of truth* [5]. Silayoi and Speece [2], and McDaniel and Baker [6] suggest that how consumers perceive the subjective entity of products, as presented through communication elements in the package, influences their choice. In turn, this perception may be the key to success for many marketing strategies [7].

While on the shelf, the product competes with many other offerings. Although occasionally minimalist design is appropriate for some brands and packages [8], in the majority of cases the products must figuratively jump out at the consumer in order for the consumer to select it from the shelf [9]. Orth and Malke-witz [10], Schoormans and Robben [11], and Meyers and Lubliner [12] underscore the importance of package design and suggest that even the same products produced by different brands should use different package designs to appeal to consumers.

Underwood and Ozanne [4], Underwood *et al.* [13], and Ampuero and Vila [14] demonstrated that visuals on the package can be a strategic method to differentiate one's product as pictures are more effective

stimuli compared to words. Furthermore, consumers process visual information faster and easier, particularly in situations with low involvement with the product [15,16]. For example, a part of the visual image of a package, its colors, plays a very important role in consumer preferences. Grossman and Wisenblit [17] and Madden *et al.* [18] suggested that colors often create potentially strong associations for consumers, driving their brand preferences.

One of the ways to design winning packages involves *experimentation with consumers*. Experiments lie at the very heart of new product development (NPD) and thus are connected to corporate values, habits, strategies, and organizational structures [19–23].

A traditional way to experiment with package design usually involves acceptance testing on the late stages of design when consumers just choose between a few complete package executions created by a designer, usually in focus groups [24–27]. Silayoi and Speece [2] and Moskowitz *et al.* [28,29] criticize this approach as suffering from subjectivism of designer opinion leading to only very few final packages to be chosen for testing. They suggest that experimentation should start at early stages of development.

One of the forms of experimentation with consumers in the early stages to find their preferences is conjoint analysis [30–32]. Whereas, substantial research has been done in using conjoint analysis for package design [2,33–36], the field is still developing.

This article shows how structured experimentation (based on conjoint analysis) in the form of rule developing experimentation (RDE) provides designers with a disciplined approach in early stage development to choose from the possible design features and their combinations. These designs, created out of the designer's talent, are then systematically explored to discover what works for a package design and what does not [37–39].

RULE DEVELOPING EXPERIMENTATION AND ITS APPLICATION TO PACKAGE DESIGN

RDE [40–42] is a structured methodology of consumer-based experimentation with conceptual prototypes which is applicable to NPD and other areas. RDE is derived from the consumer-driven proactive approaches to structured experimentation researching consumer preferences on the conceptual level utilizing partial profile conjoint analysis with incomplete concepts (concepts having zero conditions [28]) based on a special type of fractional main effects, experimental designs—isomorphic permuted experimental designs (IPED) [43]. RDE was gradually built in parts by multiple parties and formalized into a cohesive approach in Gofman and Moskowitz [38,42,43], Moskowitz and Gofman [40,44,45], and Moskowitz *et al.* [46–48] in cooperation with Prof. J. Wind (Wharton Business School).

In a wider business meaning, RDE is a systematized solution-oriented business process of experimentation that designs, tests, and modifies alternative ideas, packages, products, or services in a disciplined way using experimental design, so that the developer and marketer discover rules and patterns showing what appeals to the customer, even if the customer cannot articulate the need, much less the solution [40].

In RDE, as in other conjoint analysis-based approaches, the input materials are organized into attributes—groups of similar themed elements [49]. RDE usually utilizes Plackett Burman [50] or similar experimental designs with the elements arranged into experimentally designed prototypes (concepts) based on IPED. The IPED facilitates individual (for each respondent) unique sequences of prototypes (subject to statistically possible limits depending on the number of the categories and elements), creating a platform of conceptual prototypes testing in widely varied contexts of different combinations. This helps to overcome multiple problems of the traditional conjoint analysis approaches identified in Moskowitz *et al.* [28] and Gofman [41]. Particularly, due to having zero conditions, the IPED

enable conjoint analysis to estimate the absolute values of the utilities rather than the relative values, which are utilized in the majority of the existing methods [41,43,51]. These conceptual prototypes are presented to a representative group of consumers (respondents) to elicit their preferences (e.g., purchase intent or liking).

The solicited ratings are combined with the underlying IPED and are analyzed through a regression analysis, imputing the contribution of each individual element to predicted consumer preferences, and thus creating individual sets (for each respondent) of the utilities (part-worth contributions) of the elements also called *impacts*.

The resulting quantitative relationships between the elements and consumer preferences (rules) could be utilized by corporations to provide directions of how to increase consumer liking (purchase intent) under different scenarios. RDE quantifies the most likely combinations of ideas (features or messages) that may be acceptable to the consumer.

RDE application to graphics design is an extension of RDE methods involving just text and individual pictures, which has been widely used for the last three decades [46,48,52,53]. In package design, RDE does not replace the creative involvement. Instead, it allows a designer to sift through multiple options to facilitate the creation of new and attractive packages based on actionable consumer insights. To find a right package design and graphics, one follows the same six RDE steps used in RDE message optimization [40,54].

Step 1: Preparing Raw Materials. Identification of groups of features that constitute the target product (different options of the package features).

Step 2: Creating Test Stimuli. Process of mixing and matching the elements according to an experimental design to create a set of conceptual prototypes.

Step 3: Collecting Data with the Consumers. The actual experimentation with the consumers soliciting their responses to experimentally designed prototypes.

Step 4: Analyzing Results. Individual models for each respondent allow discovery of patterns in the data.

Step 5: Identifying Pattern-Based Latent Segments and Interactions. People's preferences differ regardless of the demographic group [55]. RDE identifies naturally occurring pattern-based latent segments of the population that show similar patterns of the utilities as well as detects any and all interactions between the elements [42,45,51].

Step 6: Applying the Generated Rules to Create New Products, Services, Offerings. Utilization of the results of RDE to optimize the ideas in the prototypes, creating a set of quantitative relationships between the elements of RDE and consumer preferences, and directions of how to increase consumer liking [54,56–60].

EMPIRICAL STUDY

The case study demonstrates this approach using the example of a package for yogurt. Rather than create a single package for evaluation, the designer creates a template with various features (e.g., picture of the flavor ingredient), and several options for each specific feature in the template. The goal then is to identify what drives consumer interest, and what does not.

RDE requires the creation of multiple packages based on an experimental design. In the example described, the target package is divided into four areas (Fig. 1): main picture (flavor), fat content, health message, and live cultures. All of the alternative executions of a specific feature should match the outlines of each other, and fit the outlining package (in the center of Fig. 1).

Each feature of the package can be thought of as a transparency layer, somewhat similar to Adobe Photoshop layers. The features of the project are transparent everywhere except for the key object of the layer. For example, in Fig. 2 you can see the yogurt package without variable features (template) and four layers with individual features positioned on each other. The outlines of the

package in each layer in Fig. 2 are shown just to demonstrate the component's positioning on the background package. In actual layers, the area outside a particular component is completely transparent.

Each option was created on a transparent layer with the feature positioned properly to allow correct matching during overlaying. All the surface bending was consistently captured inside each option based on a single template, shown in the middle of Fig. 1. The result is a set of graphically realistic pictures, assembled by the principle of RDE.

The computer (browser) superimposes these transparencies according to the RDE design, thus creating different executions of the experimental packages in real-time. Each new combination defined by the RDE design corresponds to a different package. Over the course of the interview, the participant evaluates many different combinations of options. The participant never sees the individual transparencies, but only complete packages (as on the right of Fig. 2).

A very important difference from a text-based RDE is the need for a filler background image for the situations when the package on the screen occasionally must be without an option, as required by the experimental design having zero conditions. The currently accepted solution [37,39,61,62] places a bare package (package without variable features) in the back of each screen, behind all the layers. This way, a zero condition (the absence of an option in the design) does not create a disturbing image with "holes" in it. The background image of the bare package makes the test stimulus on the computer screen be meaningful to consumers, even if it occasionally has an element missing.

Analysis

The objective of RDE analysis is to estimate the impact of each individual element (and optionally the interactions between them) along with the additive constant which could be interpreted as the baseline interest in the product (in the context of the specific experiment). Adding the individual impacts of the selected elements to the corresponding baseline allows a designer to compare the estimated interest (or purchase intent) of

Figure 1. The layout of the yogurt package with placeholders for four attributes and individual elements (not to scale).

the packages optimized for different groups of consumers.

RDE generates individual equations or models relating the presence/absence of each of the design features to the respondent's rating. The model, thus, shows how every package element drives the response (e.g., a rating "1 = Not interested → 9 = Very interested").

Different RDE applications might use various scales and recordings. In many RDE, the respondent ratings are assigned on a 9-point scale. In this case-study, the 1–9 ratings are recoded into binary values: ratings of 1–6 are recoded to 0 (the respondent was not interested, or marginally interested); ratings of 7–9 are recoded to 100 (the respondent was interested).

Figure 2. The yogurt package without variable features (left), and four layers with individual features positioned on each other and the resulting package (right) (the outlines of the package on the layers are shown just to demonstrate the component's positioning on the background package. Gray area is transparent).

Table 1. Norms for the Additive Constant and the Utilities.

<i>Additive</i>	
<i>Constant</i>	<i>Interpretation</i>
>60	Respondents are very predisposed to the product
50–60	About half of the respondents are very positive
40–50	Respondents accept the idea
30–40	The elements need to do the work
<30	The product is a commodity and the elements must do the work
<i>Utility score</i>	
	<i>Interpretation</i>
>15	The element performs exceptionally well
10–15	The element performs well
5–10	The element breaks through the clutter
0–5	The element is barely effective, if at all
<0	The element actively detracts from acceptance

[Source: Moskowitz *et al.* [28]]

The key to understanding the data for product and package development is the impacts of the individual elements. The norms for interpreting utility scores and additive constants are listed in Table 1 (assuming the above conversion to 0–100 rating scale). Here the numbers are conditional probability (percentage) of people being interested in buying the product described. Additive constant in conjoint analysis with incomplete concepts is a baseline interest of respondents in the idea of the product (without any elements present).

Table 2 contains the results of the regression analysis of the data collected for the case study.

Total Panel (Average across All Respondents). For the total panel, the constant (a general predisposition to purchase the product if no elements are shown) is very low (+8), which is normal for graphical RDE projects (a package without elements makes little sense) [28,37,56]. The best performing elements (by far) are the flavor pictures with Strawberry and Blueberry on the top of the list (+32 and +29, respectively) with Chocolate slightly trailing them (still a very

impactful +21). Among the flavors, Coffee is the lowest performing element yet with a respectable +10 impact.

The rest of the elements have impacts in the single digits with “contains health-giving probiotic cultures,” “all from the finest natural ingredients,” and “fat free” on the top of the list (excluding the flavors). Figure 3 shows a graphical representation of the impacts of the elements (sorted by the value of the impacts).

Optimizing for the Genders. There are some notable differences between the genders in how they perceive the elements in this study, although the genders were not represented equally in the panel. The constant is low and almost the same for males and females. The biggest differences are observed in how flavors influence their purchase intent. Whereas Coffee has almost the same moderate impact (+9 and +10 for males and females, respectively), the rest of the flavors show much bigger differentiation. The most popular overall flavor, Strawberry, increases men’s purchase intent by a whopping +41% and women’s by +30%. Similarly, Blueberry has +38% impact on men versus +27% on women. Chocolate is more liked by females (+22 vs +16). The least exciting is Vanilla (+8 for men vs +15 for women). Other differences are less expressed (possibly due to an uneven number of respondents in each of the groups).

Subgroups Analysis. At the end of the survey, after the RDE part, respondents answered some demographics and self-profiling questions. One of the questions was how they define their diet—“Not at all healthy,” “Somewhat healthy,” “Healthy,” and “Very healthy.” For the purposes of the analysis, we combined the first two options into one “Less healthy diet” and the last two options into “More healthy diet.”

The constants are quite different for the groups. Less healthy-oriented dieters have a much higher predisposition to buy yogurt as compared to more healthier-oriented ones. Possibly, people on a good diet are not looking for a new yogurt as they might have a preferred brand already, whereas people

Table 2. Performance of Options for the Yogurt Packaging Study (Sorted by Element Code).

		Gender			Diet		Segments	
		Total	Male	Female	Less Healthy	More Healthy	Seg 1	Seg 2
	Base size:	140	27	113	76	62	67	73
	Constant:	8	6	8	18	-4	7	8
A1	From whole milk	2	-3	4	2	4	1	4
A2	Half the fat	4	4	4	3	5	1	7
A3	50% less fat	7	6	7	5	10	2	12
A4	Fat free	8	9	8	5	13	9	7
A5	Light with less fat	4	3	4	5	4	0	8
B1	All natural	5	5	5	4	8	-2	12
B2	100% natural	7	12	6	5	10	0	13
B3	Organic	2	2	2	1	4	-7	10
B4	No artificial anything	6	9	6	4	11	-1	14
B5	All from the finest natural ingredients	8	7	8	5	12	1	15
C1	Chocolate	21	16	22	20	24	35	8
C2	Coffee	10	9	10	4	17	21	-1
C3	Blueberry	29	38	27	21	40	48	13
C4	Strawberry	32	41	30	28	36	52	14
C5	Vanilla	14	8	15	10	18	23	5
D1	Contains friendly balance bacteria	5	8	4	2	8	2	8
D2	Contains probiotic bifidus	7	10	6	4	10	4	10
D3	Contains health-giving probiotic cultures	9	9	9	5	13	4	13
D4	Live bio-cultures inside	3	8	2	1	6	2	5
D5	Contains five of the best probiotic cultures	6	7	5	4	8	1	10

Notes: The numbers are conditional probability of the elements increasing purchase intent of respondents if shown. The constant is the baseline purchase intent if no elements are shown. "Less healthy" diet is a combination of respondents self-reported having a nonhealthy and somewhat healthy diets. "More healthy" diet is a combination of respondents self-identified having health and very health diets. Seg 1 is Segment 1 "Flavor-centric." Seg 2 is Segment 2 "Health oriented."

on a less healthy diet might think about improving it. Furthermore, as compared to less healthy dieters, more healthy eaters prefer many healthier options such as fat free yogurt (+13 vs +5); 100% natural (+10 vs +5); all natural (+8 vs +4); 50% less fat (+10 vs +5). In fact, all the elements in the ingredient and fat level attribute are preferred by healthier eaters versus less healthy dieters, which make sense.

The biggest differences are in the flavor category. In absolute values, more healthy dieters prefer every flavor more versus unhealthy eaters. By far, berries increase purchase intent in a more healthy diet (Blueberry is +40 vs +21 and Strawberry +36 vs +28). Chocolate seems to be liked

very much by both groups but not to the level of berries (+24 vs +20).

In addition to insights obtained from this particular analysis, the latter tabulation of the data provides a common sense validation of the approach.

Mind-Set Segmentation. Consumers are not all created the same. People's preferences differ substantially. Most traditional approaches divide people based on some demographic, lifestyle, or purchase behavior criteria [63–65]. A more effective approach for design and development divides people based on their mind-sets emerging from the patterns of their utilities in conjoint analysis projects [49]. People in the same mind-set

Figure 3. Performance of the elements for the total panel sorted by the element code (only elements that are not neutral are shown).

segment like similar package design features or products. We can cluster respondents based on the patterns of their responses and try to optimize the package for each segment [28].

The segmentation analysis revealed two substantially different mind-sets of the consumers. Both segments have virtually the same constant (+7 and +8). Yet, there the similarities end.

Segment 1: Flavor-Centric. likes virtually all flavors (which explains its name)—from a phenomenal +52 (Strawberry) and +42 (Blueberry) to superior +35 (Chocolate) to excellent +23 (Vanilla) and +21 (Coffee). By far, this segment prefers berry-flavored yogurt. Nothing else seems to interest this segment in yogurt packages. Except for a moderately positive “fat free” feature (+9), the rest of the elements are neutral for this segments, except for a surprising (−7) for “organic.” Possibly, this segment is skeptical to this type of marketing messages. This might explain its indifference to the rest of them as well.

Segment 2: Health-Oriented. is a very different group of people. Although it does not show such huge impacts as Segment 1 does for flavors, the segment is very consistent in its preferences. Everything that communicates health scores positively with the people from this segment. All elements from the “ingredients” (attribute B) scored high: “All from the finest natural ingredients” (+15) to “organic” (+10). Although Segment 1 does not pay as much attention to flavors, two of the elements from attribute C (“Flavors”) scored high: “Strawberry” (+14) and “Blueberry” (+13). Those are the only flavors that are associated with healthy diets. Healthy ingredients (attribute D) are also important for this segment. Four out of five elements scored high: “contains health-giving probiotic cultures” (+13) to “contains friendly balance bacteria” (+8). Fat level (attribute A) is also an important issue for them. “50% less fat” adds +12 points to the purchase intent. Except for the “from whole milk” which has a neutral impact for this segment, the

Figure 4. Performance of the elements related to fat content (shown for the total panel; consistently representative for all other subgroups).

rest of the elements from attribute A are positive (+7 to +8).

This type of segmentation afforded by individual models in RDE are actively utilized by businesses. In a typical case, a manufacturer would consider creating a separate product for each segment to maximize the appeal to the different mind-sets of the consumers. Otherwise, it will still do well creating a single product optimized for the total panel. In that case, although capturing fewer buyers than with individually optimized packages for each segment, it will create a more appealing product than one based on a pure guess.

Effect of the Fat Content Messages Wording.

A product developer could use the data to find better manufacturing options, while a marketer explores more efficient messages. For example, Fig. 4 shows the findings related to the fat content messages.

The relative values of impacts in Fig. 4 are consistent across all the subgroups. Whereas "Half the fat" is virtually identical to "Light with less fat," "50% less fat" is clearly a more efficient driver of purchase intent than the semantically identical "Half the fat" message for all the subgroups. "Fat free" is only marginally better performing comparing to the latter messages.

In the context of the current study, the respondents clearly prefer concrete, numeric presentation of the fat content over its equivalent verbal presentation. Yogurt manufacturers could choose the "50% less fat" option to capture more buyers.

SUMMARY

The utilization of RDE to graphical elements allows applying the power of conjoint analysis to understand consumer preferences of packages in the early stages of development. Following the idea of layers and applying individual permuted experimental designs to sets of the layers, allows for dynamic creation and evaluation of multiple experimentally designed packages, thus reducing the subjectivity of the designer through deeper consumer involvement in the process in the early stages.

The process should be viewed as providing important and timely input about consumer preferences to designers. It does not replace the artistic talent in any way. Quite to the contrary, it helps to narrow the multiple choices available for the designer. Particularly, this approach could be utilized as a parsimonious way to create appealing products in mature categories where differentiation is difficult and the budgets are small.

This approach resolves the problems related to consumers being unable to describe what they need. At the same time, it overcomes the complex and intervened statistical problems related to traditional methods of conjoint analysis utilizing a single experimental design for a project.

Computing Center of Russian
Academy of Science, Moscow,
Russia

DEVELOPMENT OF OPERATIONS RESEARCH SURVEY

Russian Scientific Operations Research Society (RSORS) was organized at the First International Moscow Conference on Operations Research (OR) in 1996. This event was an important stage in rapid successful development of OR in the Soviet Union and consequently in the Russian Federation (RF).

In 1964, under the patronage of the President of the Academy of Sciences (AS) of the Soviet Union, a department of applied problems was created. It was headed by Popov and Pospelov, who initiated investigations on OR within the AS. The investigations were conducted in three AS institutes: Computing Center Academy of Sciences (CCAS) in Moscow (where this direction was headed by Moiseev), Mathematical Institute of AS Siberian branch in Novosibirsk (where Zhuravlev led the research), and Cybernetics Institute of Ukrainian AS in Kiev (founded by Glushkov). Additionally, the AS council, which was headed by Glushkov was established, and publications of OR periodicals began.

The department of OR was established in CCAS in 1966. It was run by Germeier. He also led the OR department created at Lomonosov Moscow State University (MSU) as a division of Computation Mathematics and Cybernetics Faculty in 1970. The technical committee of the OR society of the Soviet Union was founded at the CCAS in 1972 and registered in IFORS. Moiseev was appointed its chairman.

The collapse of the USSR caused scientific links between the former Soviet Republics to disappear resulting in the destruction of many scientific societies. Some OR scientists went on to solve Russia's organizational and technical problems while others further continued testing the OR theory. Many of these scientists soon realized the necessity of broader scientific contacts and restoration of the former scientific ties. Russian scientists desired to unite their scientific efforts and enter into international exchange of ideas, research results, and experiences encompassing OR.

ESTABLISHMENT OF THE SOCIETY, ORGANIZATIONAL STRUCTURE, AND PUBLICATIONS

In 1996, the 50th year since the formulation of OR, the first Moscow International Conference on OR (10–13, April 1996) was held in Russia under the sponsorship of the Russian Foundation for Basic Research and the Russian Academy of Sciences (RAS). The motto of the conference was "History. Beginnings. Unification." The RSORS was established at this conference, and its governing and controlling bodies were elected. The conferences' documents and theses were published and are now available on the Internet [1]. In particular, they contain protocols, the charter, the list of founders, and other documents of the RSORS. Moiseev was elected the Honorary President, and Krasnoschekov was elected President of the RSORS.

The Moscow International Conference on OR became triennial. Together with the Conference, RSORS holds the meetings of its members and elections. Thus, every third year the Conference elects the Council and the Council elects the President of the RSORS. In the conferences held so far (second—November 17–20, 1998; third—April 4–6, 2001; fourth—September 21–25, 2004; fifth—April 10–14, 2007), Krasnoschekov was reelected President; he has thus been

working continuously in the same location for more than 13 years.

At present, the organizational structure of RSORS is as follows: The President of RSORS is Krasnoschekov, the Vice-Presidents are Savin and Malashenko, the Chairman of the Council is Zhuravlev, the Chairman of the Auditing Committee is Flerov, the Scientific Secretary of RSORS is Pospelova, and Nazarova is a secretary. Office of RSORS: off. 230, Vavilov str, 40, Moscow, 119 333, Russia. Phone: +7(499)135-01-70. Fax: +7(499)135-54-29. Organizational web site of RSORS is <http://www.ccas.ru/RSORS>

Both individual scientists and scientific groups hope that the society will effectively aid in the international exchange of ideas and new results accumulated during the recent years. OR specialists in Russia have a wide range of interests and the new scientific society should reflect this variety and use it for the benefit of the science.

Scientific works in the various spheres of OR are mostly published in the following scientific journals of RAS: *Journal of Applied and Industrial Mathematics* [2] and *Journal of Computer and Systems Sciences International* [3]. In addition, the *Journal of Mathematical Modeling* [4] contains a special OR subdivision. The *Journal of Computational Mathematics and Mathematical Physics* [5] calls attention to the works on optimization methods. *Moscow University Computational Mathematics and Cybernetics* [6] is another journal containing a special OR section. Most fundamental OR works are published by the CCAS in the sequential issues of *Communications on Applied Mathematics* [7]. Besides the Moscow International Conference, RSORS permanently holds conferences on OR under the sponsorship of the Siberian branch of AS [8].

SCIENTIFIC ACHIEVEMENTS OF THE RUSSIAN SCIENTIFIC OPERATIONS RESEARCH SOCIETY

Germeier contributed greatly to OR theory through his formulation and development of the principle of guaranteed result [9].

He investigated nonantagonistic games, where players have incomplete information on payoff functions of each other. Together with Moiseev, he set the foundation of hierarchical games [10] (see also the sections titled "Game Theory" and "Game Theory: Extension and Development" in this encyclopedia).

The famous Russian scientist, Moiseev made significant contribution to OR through the development of methods of analysis of earth's biosphere and environmental protection. The estimation of consequences of nuclear war obtained on the basis of his model and under his leadership was recognized worldwide as the nuclear winter phenomenon [11]. This result can be considered as one of the most outstanding examples of practical applications of the OR theory (see also the sections titled "Environmental Planning and Energy" and "Military Applications" in this encyclopedia).

The design of complex engineering systems gives rise to multicriterion tasks. Solving these tasks is a difficult mathematical problem. The well-known scientist, Krasnoschekov and his coworkers proposed mathematical methods of effective (Pareto optimal) solution comparison [12]. The new approach permits to select the most promising options from the set of Pareto optimal solutions. This was a fundamental contribution to OR methods. Krasnoschekov has also contributed immensely to OR theory through his principles of mathematical modeling [13]. These ideas were successfully implemented into computer-aided design systems for aircraft, financial markets, semantic search, and analysis of national language texts (information technology "Keys to Texts" [14]), gas and oil field development (see also the section titled "Simulation Modeling and Analysis" in this encyclopedia).

A new direction of research emerged under the leadership of Petrov, in the CCAS, in 1975. The system analysis of developing economy [15] provides a unique platform for synergy of methods of mathematical modeling of complex systems and achievements of the modern economic theory. These models were

similar to computable general equilibrium models, which became popular in the 1990s, and paid more attention to singularities of economic mechanisms of the system under consideration. The interval logic of seemingly paradoxical economic processes became evident because of these models. These works converted the “annals” of the Russian economic reforms into the language of mathematical models [16,17] (see also the section titled “Simulation Modeling and Analysis” in this encyclopedia).

The unified model of analysis of efficiency and vitality of multicommodity networks was developed in the OR department of CCAS recently. Classical OR constructions and methodological approaches (flows in networks, game theory, max-min principle, and the principle of guaranteed result) were exploited and developed in the framework of the model for the first time. On the basis of this model, selected problems of analysis and synthesis, reliability and vulnerability of telecommunication, and power networks were successfully solved [18]. One of the most recent developments is application of the OR methodology in the power energy sector of the RF [19] (see also the sections titled “Graph Characterizations,” “Computer and Network Reliability” and the article in this encyclopedia).

OR models often result in rather complicated and sophisticated problems for which special numerical methods are required. Many RSORS members specialize in developing such methods (see Refs 20 and 21). Germeier’s works in game theory are now being developed further by Kukushkin and his other pupils [22]. The present chair of the MSU OR department, Krasnoschekov and his collaborators explore evolutionary models of population behavior and their applications in political science (social behavior), auction theory for homogeneous goods markets, option theory, tax enforcement problems, actuarial mathematics, and optimization theory and techniques. Some of the results obtained are published in the above-mentioned journals and the conference materials; also see Refs 23–29, and the sections titled “Collective Choice

and Social Utility Theory” and “Financial Engineering” in this encyclopedia.

The work of the OR department at the MSU is supported by RF President Grant from the “Program for Support of Leading Scientific Schools.” In addition to scientific research, the department educates professional specialists for the entire country under leadership by Krasnoschekov. Under the supervision of RSORS members, dozens of PhD theses were defended and OR science received strong positive impact during the last 13 years.

RSORS members continue active investigation in all OR divisions. They are developing fundamental ideas and approaches proposed by both Russian and foreign scientists, and contribute to further advancement of the contemporary science. The next Moscow International conference on OR will take place in October, 2010 [30]. It will summarize the new achievements in OR development in Russia and other countries.

SADDLEPOINTS AND VON NEUMANN MINIMAX THEOREM

BEHZAD HEZARKHANI
Faculty of Business
Administration, Memorial
University, St. John's,
Newfoundland, Canada

Two-person zero-sum (TPZS) games are win-lose games, whatever is won by one player is lost by the other player. In this respect, TPZS games are completely competitive games. That is, players cannot hope to improve their situation by any cooperation. Instances of such games are pervasive in a variety of environments: from games played for fun; to business, political, and military decision making environments. In this vein, analysis of TPZS games can provide useful insights into the actual circumstances.

TPZS games can be abstracted into simple models. This makes their analysis a reasonable starting point in studying game theory. Coincidentally, game theory as it is known today has been founded after the exposition of revealing characteristics of TPZS games in 1926 by John von Neumann [1] and the seminal book in 1946 by John von Neumann and Oskar Morgenstern [2].

This section introduces the basic properties of TPZS games and presents their general solution concepts. The structure of this section is as follows. Some preliminary issues about TPZS games, including main assumptions and simplifications, have been addressed in the section titled "General Characteristics of TPZS Games," which will set the ground for the upcoming analysis. The section titled "Minimax and Maximin Strategies as the Security Strategies" introduces the maximin and minimax strategies as the security strategies for players. In the section titled "Strictly Determined Games and Saddlepoints" the strictly determined TPZS games have been discussed. The section titled "Nonstrictly Determined Games and Mixed Strategies" addresses the nonstrictly

determined TPZS games and the concept of mixed strategies along with the von Neumann's minimax theorem that provides a general solution concept for TPZS games.

GENERAL CHARACTERISTICS OF TPZS GAMES

A game is the situation when some persons (i.e., players) are faced with decision making problems, while the outcomes to each person are also affected by the decisions made by the others. In two-person games, this interrelation of decisions exists only between two players. If the outcomes of the game to players are exactly opposite in each case, the game is zero-sum. For example, if the outcomes of a game are the dollar amounts that each player gains or loses, then the game is zero-sum if the amount that one player gains is exactly equal to the amount which the other player loses.

In TPZS games, it is assumed that when players are making their decisions, each has a finite number of different moves to choose from. The attitudes of players are also such that they prefer higher gains over lower gains or equivalently, lower losses over higher losses. Moreover, they make their decisions in accordance with their preferences; otherwise, they would not be *rational*.

The players have certain information about the game they are playing. In particular, they are assumed to know the moves available to the opponent in addition to their own available moves. The players are also fully aware of the outcomes of the game in all possible combinations of their joint moves. Additionally, the players know that they are in equal situations in terms of their knowledge about the game. These assumptions are referred to as *complete knowledge*.

The difficulty of a game situation is due to the fact that each player has to choose his or her moves without knowing the other player's

actual choice. Therefore, the question faced by each player is which move to choose. Hence, analysis of the game should elaborate on the players' choices of their moves. That is the concept of *solution* to a game.

The above characteristics are assumed to be present in all TPZS games even though they are not explicitly stated. Let us consider some examples of TPZS games.

Example [Rock–Scissor–Paper]. The game of rock–scissor–paper (R–S–P) is played as follows. Each player should choose a hand posture from three possibilities: (i) fist representing a piece of rock, (ii) flat hand representing a piece of paper, and (iii) fingers held in a “V,” representing a scissor. Then, the hand postures are shown at the same time. The winner is determined according to these rules: Rock breaks scissor, scissor cuts paper, and paper wraps rock. For example, if a player chooses rock while the other chooses scissor, rock wins, and so on. If both choices are the same, it is a draw. The winner gets one dollar from the loser.

Example [Marketing Strategy in Duopoly]. Two high-tech companies offer wireless phones in a regional market. They used to hold equal shares of the market just before the network provider installed more advanced network equipment. Consequently, both companies designed new products which took advantage of the current technology. However, they need to decide their marketing strategies. The companies have three options: to advertise (which requires significant amounts of investments), to offer discounts (which require less amounts of investment), or not to invest in marketing. If they take the same strategies, their market shares remain the same. However, if they take different strategies, the company that invests more gains more shares of the market.

We return to these examples in greater detail in forthcoming sections.

Formal Description of the Game

Despite the variety of game situations, certain aspects of TPZS games can be represented in a condensed and standard

manner that lends itself to formal analysis. In TPZS games, the participating persons are referred to as *players* 1 and 2, respectively. For referencing convenience, we refer to player 1 with male pronouns and player 2 with female pronouns throughout the rest of this section.

The sets of possible moves that players can choose from constitute an important characteristic of the game. A convenient way of representing the players' moves is through the concept of *strategy*. In games that require each player to make just one move, a strategy is identical to a singular move. However, in multistage games—where the players are required to make several moves—a strategy represents a sequence of moves, one for each stage, for a player.

The collection of a player's strategies is called the *strategy profile* for that player. We denote the strategy profiles for players 1 and 2 with S and T , respectively. Since the total number of strategies for each player is finite, we denote the strategy profiles as

$$S = \{s_1, \dots, s_n\},$$

$$T = \{t_1, \dots, t_m\},$$

where n is the total number of strategies for player 1 and m is the total number of strategies for player 2. Every individual element of a strategy profile is referred to as a *pure strategy*.

In our R–S–P example, the strategy profiles for both players are simply rock, scissor, and paper hand postures. In the marketing strategy example, the strategy profiles are comprised of three pure strategies: to advertise, to offer discounts, and to do nothing. Note that in general, players can have different strategy profiles.

Next step is to consider the outcomes of the game. The outcomes of the game—based on the players' choices of their pure strategies—is determined through a *payoff function* denoted by π . The payoff function then determines the values of pairs of pure strategies to the players. In general, this payoff is measured in units of *utility*. Therefore, the payoff of a pair of strategies shows the units of utility gained or lost by the players under the choice of those strategies.

In this vein, $\pi_1(s_i, t_j)$ shows the payoff to player 1 if he chooses strategy s_i and, at the same time, player 2 chooses strategy t_j . A game represented by the sets of strategies (strategy profiles) and the corresponding payoff function is a *game in strategic form*.

A game in strategic form can be shown by a $n \times m$ matrix, where the rows represent the pure strategies for player 1 and the columns represent the pure strategies for player 2. Each element of the matrix is a pair showing the respective payoffs to both players. Such a matrix is called the *game matrix*. Table 1 depicts the general game matrix in two-person games.

In zero-sum games, we can further simplify the presentation of game matrix. In TPZS games, by definition, the sum of payoffs to the players corresponding to each matrix element is zero; that is,

$$\pi_1(s_i, t_j) + \pi_2(s_i, t_j) = 0$$

for every s_i and t_j in S and T , respectively. Therefore, in TPZS games, for all pairs of strategies, the payoff to player 2 is the opposite of player 1's payoff; that is, for every s_i and t_j in S and T .

$$\pi_2(s_i, t_j) = -\pi_1(s_i, t_j).$$

Thus, having either player's payoffs, we can immediately infer those of the other player. Consequently, we conform to the following convention in presenting the TPZS game matrices: we exclude the player 2's payoffs from the game matrix and only depict those of player 1. We also skip the superscript 1 from the notation of payoff function. The corresponding game matrix is given in Table 2.

Table 1. General Game Matrix in Two-Person Games

	t_1	$\dots$	t_m
s_1	$\pi_1(s_1, t_1), \pi_2(s_1, t_1)$	$\dots$	$\pi_1(s_1, t_m), \pi_2(s_1, t_m)$
$\vdots$	$\vdots$	$\ddots$	$\vdots$
s_n	$\pi_1(s_n, t_1), \pi_2(s_n, t_1)$	$\dots$	$\pi_1(s_n, t_m), \pi_2(s_n, t_m)$

Table 2. The Game Matrix in TPZS Games

	t_1	$\dots$	t_m
s_1	$\pi(s_1, t_1)$	$\dots$	$\pi(s_1, t_m)$
$\vdots$	$\vdots$	$\ddots$	$\vdots$
s_n	$\pi(s_n, t_1)$	$\dots$	$\pi(s_n, t_m)$

Note that the matrix elements in Table 2 represent the payoffs to player 1. Accordingly, the game matrix in TPZS games can be depicted by the $n \times m$ matrix Π , whose element in row i and column j shows the payoff to player 1 if he chooses his i th strategy and player 2 chooses her j th strategy. The game matrix for our marketing strategy example is presented in Table 3.

A straightforward generalization of TPZS games is two-person constant-sum (TPCS) games. In TPCS games, the sums of players' payoffs under all strategy pairs are constant. In fact, every constant-sum game can be reduced to a zero-sum game. Consider a K -sum TPCS game. By definition, for every i and j , we have

$$\pi_1(s_i, t_j) + \pi_2(s_i, t_j) = K.$$

Then, using the transformation $\tilde{\pi}_2(s_i, t_j) = \pi_2(s_i, t_j) - K$, we can construct an equivalent zero-sum game (since $\pi_1(s_i, t_j) + \tilde{\pi}_2(s_i, t_j) = 0$). The validity of this transformation is due to that fact that linear transformation of players' payoff functions does not alter the structure of their preferences.

MINIMAX AND MAXIMIN STRATEGIES AS THE SECURITY STRATEGIES

Consider the game matrix for our marketing strategy example in Table 3. Obviously, player 1 obtains the highest payoff when he

Table 3. The Game Matrix for Marketing Strategy Example

	Advertise	Discount	Do Nothing
Advertise	0	5	10
Discount	-5	0	5
Do Nothing	-10	-5	0

chooses to advertise and his opponent does nothing. This would result in 10 additional market shares for player 1. But should player 1 choose his first strategy hoping to achieve this payoff? Well, not necessarily. This is because player 2 is also taking her situation into consideration. Nevertheless, the strategy pair that gives player 1 the maximum gain costs player 2 the maximum loss of 10 less market shares. How should players select their strategies then?

Since the players cannot simply aim for their best payoffs, one appropriate alternative for them is to select the strategies, which guarantee a minimum amount of gain, or equivalently a maximum amount of loss. These strategies are called *security strategies*.

In the above example, player 1 can verify that if he chooses to advertise, the minimum payoff he could get is to acquire no additional market shares: that happens if player 2 also advertises. So, not knowing the choice of player 2, the worst payoff to player 1 under his first strategy is 0. With the same logic, the minimum payoff to player 1 if he chooses to offer discounts is losing five market shares to player 2, and if he chooses to do nothing, the minimum payoff is losing 10 market shares to player 2. Then, by choosing his first strategy, player 1 could maximize his minimum payoff regardless of player 2's strategy ($\max\{0, -5, -10\} = 0$). Therefore, the security strategy for player 1 is to advertise. The payoff to player 1 in this case is called the *value of the game to player 1*. The latter can also be interpreted as the "gain-floor" for player 1 and he must not win less than that.

To depict this line of reasoning, we define v_1 as the value of the game to player 1 such that

$$v_1 = \max_{s_i} \min_{t_j} \pi(s_i, t_j).$$

In other words, v_1 is the payoff that player 1 gets by choosing the strategy s_i that maximizes the minimum payoff to him under the choice of that strategy.

Considering the game from player 2's view point, we can define her security strategy in a similar way. However, note that the values in the game matrix are, in fact, player 2's antipayoffs or simply losses. Therefore, security strategy for player 2 is the strategy

that minimizes her maximum loss, that is, her "loss-ceiling" (she must not lose more than that). We define v_2 as the value of the game to player 2 such that

$$v_2 = \min_{t_j} \max_{s_i} \pi(s_i, t_j).$$

In the marketing strategy example, the maximum loss for player 2 if she chooses to advertise is zero. The same values for player 2 under her second and third strategies are 5 and 10, respectively. Hence, the security strategy for player 2 is to select her first strategy that results in the loss-ceiling of 0 ($\min\{0, 5, 10\} = 0$).

In TPZS games, the values of the game for the players are related in a particular way. Theorem 1 expresses this relationship.

Theorem 1. *In all TPZS games, $v_1 \leq v_2$. That is*

$$\max_{s_i} \min_{t_j} \pi(s_i, t_j) \leq \min_{t_j} \max_{s_i} \pi(s_i, t_j).$$

This relationship is quite intuitive. It expresses that player 1's secured gain (gain-floor) is always less than or equal to player 2's secured loss (loss-ceiling). The interested reader is referred to p. 219 in Ref. 3 for the proof of this theorem.

STRICTLY DETERMINED GAMES AND SADDLEPOINTS

Consider a class of games for which the players' security strategies result in equal payoffs, that is $v_1 = v_2$. In these games we define v^* as the value of the game such that

$$v^* = v_1 = v_2.$$

The strategy pair corresponding to v^* is called the *saddlepoint*. Thus, if a game has the value, then it has a saddlepoint and *vice versa*. In TPZS games with the value, the choices of security strategies are *optimal* for the players. The optimality of these strategies in these games is due to the fact that none of the players can hope to improve his/her payoff by unilaterally deviating from the choice

of security strategies. In a broader sense, a saddlepoint is also a *Nash equilibrium* [see *Nash Equilibrium (Pure and Mixed)* for more on this concept].

Games with this property are referred to as *strictly determined games*. This is because the players' optimal choices of pure strategies can be determined for these games. In other words, TPZS games with the value are *solvable* in pure strategies. A saddlepoint, then, is *the solution* of a TPZS game in pure strategies.

Once again, consider the marketing strategy example. In the previous section, we calculated the individual security strategies for the players as s_1 and t_1 . The values of the game to both players are zero, that is, $v_1 = v_2 = 0$. Since these values are equal, the game is strictly determined with the value $v^* = 0$, and (s_1, t_1) is the saddlepoint, so both players should advertise. In this situation, if player 1 anticipates that player 2 is going to advertise, the optimal choice for player 1 is still to advertise. Hence, even when the players could foresee the strategy choice of their opponent in terms of security strategies, they cannot improve their payoffs by selecting any strategies other than their security strategies.

It is possible that a strictly determined game has multiple saddlepoints. In this case, more than one pair of strategies corresponds to v^* and the choices among them are equally desirable for both players.

For example, in the game matrix presented in Table 4, there are two saddlepoints (s_2, t_1) and (s_2, t_3) . The corresponding value of game is 1. In this situation, we can determine the game by stating that the player 1 chooses his second strategy while the player 2 selects either her first or third strategy. The outcome, however, is the same in both cases.

Table 4. A Strictly Determined Game with Multiple Saddlepoints

NONSTRICTLY DETERMINED GAMES AND MIXED STRATEGIES

In the previous section, we addressed a special class of games with the property of value. However, not all TPZS games are as such. The games without the value—and consequently no saddlepoint—are called *nonstrictly determined games*. In these games, the players' choices of strategies cannot be formulated as clearly as those in the strictly determined games, that is, in terms of pure strategies.

Consider the example of R–S–P game in the section titled “General Characteristics of TPZS Games” and its game matrix in Table 5. In this game, player 1's gain-floor, v_1 , is -1 and player 2's loss-ceiling, v_2 , is 1 . The game does not have a value and consequently, there is no saddlepoint. In terms of security strategies, the choices among the three strategies do not differ for the players. Hence, the game does not have a solution in pure strategies. In other words, the optimal choices of players' pure strategies cannot be specified.

Let us discuss this issue in more detail. The game matrix in Table 6 presents a hypothetical game. Accordingly, the security strategy for player 1 is s_2 with $v_1 = 1(\max\{-1, 1\} = 1)$ and the security strategy for player 2 is t_2 with $v_2 = 3(\min\{5, 3\} = 3)$. This game has no saddlepoint because the values of the game to the players are not equal. Therefore, the choices of security strategies are not optimal in this case. To see this, suppose that player 1 decides to play his security strategy. If player 2 suspects this, she will be better off by playing her first strategy instead of her second (security) strategy. This, on the other hand, gives player 1 a chance to play his first strategy and achieve his best possible outcome. Having speculated this, player 2 can justify playing her second strategy that

combined with the choice of player 1, leads to her best outcome. It seems that when there is no saddlepoint, players could improve their payoffs by selecting some strategies other than security strategies, but at the same time, this puts them in an inconclusive situation that stems from their iterative speculations. Thus, we need to find a solution concept for the nonstrictly determined games that sheds light on these situations.

Although the solution of nonstrictly determined games cannot be determined in terms of pure strategies, we can still make further inferences about them; nevertheless, these games are still called *determined*. However, in order to develop a solution concept for these games, we need to employ an alternative view of strategy choice. The concept of *mixed strategies* provides such a view. Then, the possible solutions to nonstrictly determined games can be characterized in terms of mixed strategies.

A mixed strategy is essentially a choice of probabilities that a player assigns to the selection of his/her pure strategies. By providing a probabilistic view of strategy choices, the concept of mixed strategies considerably expands the players' strategy choice spaces. When playing a mixed strategy, a player chooses his/her strategies randomly. However, the player can decide the probabilities of these random selections. In order to provide an intuitive understanding of mixed strategies, suppose that the players have devices that can randomly suggest to them which pure strategy to choose. In the R-S-P example, assume that player 1 rolls a die in order to decide which hand posture to show. A mixed strategy for him then is to play rock if the die is either 1 or 2, play scissor in cases of 3 and 4, and play paper in cases of 5 and 6.

We can formally demonstrate a mixed strategy by a vector of probability measures that correspond to all the pure strategies of

a player. In TPZS games, mixed strategies can be shown with two separate vectors. We denote a mixed strategy for player 1 by

$$p = (p_1, \dots, p_n),$$

such that $p_i \geq 0$ for all i , and $\sum_{i=1}^n p_i = 1$. Note that the subscript i corresponds to player 1's pure strategies. A mixed strategy for player 2 is

$$q = (q_1, \dots, q_m),$$

such that $q_j \geq 0$ for all j , and $\sum_{j=1}^m q_j = 1$. Again, j indexes player 2's pure strategies. The k th element of either of these vectors depicts the probability of playing the k th pure strategy by the respective player. The additional conditions make sure that p and q are probability vectors. If all the elements of a mixed strategy are positive, then it is a *totally mixed strategy*. Note that pure strategies can now be defined as special forms of mixed strategies, where only one vector element equals to one and all the others are zero.

Returning to the R-S-P example, a mixed strategy $p = (3/4, 0, 1/4)$ implies that player 1 plays his first and third pure strategies with respective probabilities of 3/4 and 1/4, while he does not play his second pure strategy at all. The totally mixed strategy $q = (1/3, 1/3, 1/3)$ implies that player 2 will play her pure strategies with equal probabilities of 1/3.

While the payoffs with pairs of pure strategies are given in the game matrix, at this point we need to devise a measure for quantifying the payoffs with pairs of mixed strategies. Since the mixed strategies are expressed in probabilistic form, a straightforward such measure in this setting is the *expected* payoff. The expected payoff with a pair of mixed strategies, $J(p, q)$, is defined as

$$J(p, q) = \sum_{i=1}^n \sum_{j=1}^m p_i q_j \pi(s_i, t_j).$$

In this equation, $p_i q_j$ is the joint probability that pure strategies i and j are selected by players 1 and 2, respectively. The summation over the players' probability vectors

provides the expected payoff. Note that this expected payoff is in fact to player 1 (since $\pi(s_i, t_j)$ is his), and the expected payoff to the second player is the opposite, that is, $-J(p, q)$. We can also demonstrate the latter in matrix form:

$$J(p, q) = p \times \prod \times q^T.$$

The superscript T denotes the matrix transpose operation. If we assume that both the players are indifferent between a sure payoff of S and a risky payoff with the equal expected payoff (i.e., both are risk-neutral), we can use the expected payoff function as the criterion for measuring the efficiency of players' choices of mixed strategies.

Similar to the section titled "Strictly Determined Games and Saddlepoints," we can construct the security strategies for the players, but this time in mixed form. Player 1 can reason that if player 2 discovers his choice of mixed strategy p once he chooses it, she selects her mixed strategy q so that $J(p, q)$ is minimized (so that she would maximize her expected payoff). In other words, given the mixed strategy of player 1, the worst expected payoff that he could obtain is when player 2 plays $\min_q J(p, q)$. Therefore, player 1's secure strategy is to choose his mixed strategy in a way that the latter is maximized. Thus, the security strategy for player 1 in mixed strategies is

$$\dot{v}_1 = \max_p \min_q J(p, q).$$

The reasoning process for player 2 is similar. She chooses her mixed strategy so that she could minimize losses that result from the first player's payoff maximization attitude. The security strategy for player 2 in mixed strategies is

$$\dot{v}_2 = \min_p \max_q J(p, q).$$

The dots over $\dot{v}_1$ and $\dot{v}_2$ differentiate the values of the game to the players with mixed strategies from those with pure strategies. The general relationship between the $\dot{v}_1$ and $\dot{v}_2$, that is, $\dot{v}_1 \leq \dot{v}_2$, still holds.

If $\dot{v}_1 = \dot{v}_2$, then the respective mixed strategies for the players are optimum in the

sense similar to that of the pure strategies case: none of the players could improve his/her expected payoffs by deviating from the mixed security strategies. One might suspect that similar to the case with pure strategies, $\dot{v}_1$ and $\dot{v}_2$ are not necessarily equal. In fact, Luitzen Brouwer—the great mathematician whose fixed point theorem set the ground for development of game theory—thought so. However, John von Neumann in his 1926 paper proved otherwise.

Theorem 2 [Von Neumann's Minimax Theorem]. *Given a TPZS game matrix, $\prod$, there always exists a pair of mixed strategies, p and q for players 1 and 2 respectively, such that $\dot{v}_1 = \dot{v}_2$.*

The von Neumann minimax theorem provides a very strong statement for the TPZS games; it shows that all TPZS games have optimal solutions in terms of mixed strategies. The proof of this theorem requires advanced mathematical knowledge and the interested reader may refer to p. 15 in Ref. 4. This theorem is also called *Von Neumann's maximin* theorem.

In the R-S-P game, the optimal mixed strategies for both players are to play all their pure strategies with equal probabilities of 1/3. This would result in the expected payoffs of 0 for both players. In general, the pair of optimal mixed strategies might not be unique. Then again, the choice among them can be made arbitrary because, by definition, they all have the same expected payoffs. The upcoming sections provide comprehensive methods for finding the actual solutions to TPZS games.

INTRODUCTION

Personal selling is an important marketing instrument in many industries. Zoltners *et al.* [1] report that the US economy has been estimated to spend \$800 billion on sales forces, almost three times the amount spent on advertising (\$276 billion) in 2006. Personal selling is the most effective way, especially in business markets, to learn about and assess a customer's needs, inform customers of standard and/or customized solutions, detail and demonstrate complex high-value products, handle objections, close sales and provide long-term continuing service (see also **Customer Relationship Management: Maximizing Customer Lifetime Value** in the section titled "Applications and History"). However, the high impact of sales forces on firms' sales comes at a high cost. Dartnell's *30th Sales Force Compensation Survey: 1998–1999* reports that the average company spends 10% and some companies spend as much as 40% of their total sales revenues on sales force costs.

A recent meta-analysis of previous empirical studies of personal selling sales response relationships by Albers *et al.* [2] indicates that the mean personal selling sales elasticity (corrected for methodological biases) is about 0.31, significantly larger than the

mean advertising sales elasticity of about 0.06–0.22. Thus, changes in the deployment of personal selling efforts can have large impacts on companies' topline as well as bottom lines.

OVERVIEW OF SELLING EFFORT DECISIONS

Figure 1 displays how sales resource allocation and territory design are related to other problems of sales management. Size, structure, and compensation are strategic decisions that are usually set by top management for several years. They guide lower-level, shorter-term operational planning by senior and middle management with respect to *sales territory design* and *compensation plan design*. These decisions will impact tactical selling effort allocation optimization made by front-line management (e.g., district managers) as well as individual sales representatives. Conceptually, these disaggregate decisions will be guided by local managers' and/or sales representatives' knowledge of sales response functions, that is the relationships between selling effort and sales generated from the relevant sales entities figuring in the decision; for example, market segments or individual customers/accounts. Consequently, 'response function' is shown as the root of Figure 1 because forming assessments of these relationships is a prerequisite for optimizing any of the higher-level decisions.

Figure 1 also indicates that all the decision areas are, in principle, interdependent. In particular, the selected sales force size and structure have implications for the sales territory design. Further, sales territory design impacts the actual allocation of selling effort by an individual representative. Thus, optimization of decisions at each of these levels depends on the assumptions made with respect to lower-level call allocation decision rules as well as higher-level policy constraints. These interdependencies considerably complicate the development of models for globally optimizing sales force

Figure 1. Selling effort decisions. [Source: Ref. 3, “Models for Sales Management Decisions,” in Berend Wierenga (ed.): *Handbook of Marketing Decision Models*, Springer Science + Business Media, International Series in Operational Research and Management Science, p. 166].

decisions. Not surprisingly, therefore, sales force optimization research has progressed by focusing on compartmentalized models. Examples of such models are Lodish’s [4] CALLPLAN for sales calls allocation across customers (described in more detail later in this article) assuming sales force size, structure, and territory design are fixed; and models for sales territory design that assume a fixed sales force size and structure such as those of Lodish [5], Zoltners and Sinha [6], and Skiera and Albers [7].

In the next section we provide a brief overview of research with respect to specification and estimation of sales response functions that lie at the heart of all sales force optimization models.

ESTIMATION OF SALES RESPONSE FUNCTIONS

Decision Calculus Approaches

In the early years of sales force decision modeling, the lack of appropriate objective data constrained the calibration of sales response functions. Therefore, researchers worked with the information that was available, namely subjective or judgmental data. This *decision calculus* approach rested on the logic that managers and salespeople were

already making intuitive decisions based on subjective estimates. The best known example of the decision calculus approach is CALLPLAN proposed by Lodish [4]. Lodish and his colleagues validated CALLPLAN in a field study at United Airlines [8], and reported successful applications at firms such as the Syntex Laboratories [9].

Econometric Approaches

From the late 1980s, the econometric estimation of response functions based on historical data has gained ground primarily because of the increasing availability of transactional panel data with large numbers of observations at the disaggregate or individual customer level. The bulk of the published econometric applications come from the pharmaceutical industry. Aside from data availability, another reason for the ascendancy of the econometric approach is the development of powerful econometric estimation methods and software that can handle many thousands of observations and come up with idiosyncratic estimates per response or sales coverage unit (SCU).

Functional Form

The question of the appropriate sales response functional form remains unresolved.

Should the sales response function be S-shaped as used in early decision calculus models like CALLPLAN or just concave in form?

A popular S-shaped functional form for any sales entity or control unit i in a set of I units as expressed below, was used in Lodish's [4] CALLPLAN. In Equation (1), S_i represents sales of i th entity, h_i the number of calls, and the four parameters, α_i , β_i , γ_i , and δ_i are each > 0 .

$$S_i = \alpha_i + (\beta_i - \alpha_i) \frac{h_i}{\gamma_i + h_i^{\delta_i}} \quad (i \in I). \quad (1)$$

Researchers do agree that sales response functions used in effort allocation models must eventually exhibit diminishing returns to increasing effort. Inherently nonlinear functional forms posed a challenge for econometric estimation in the early years. Thus, until about 15 years ago, econometric applications were limited to the estimation of the parameters of nonlinear aggregate sales response functions such as the multiplicative (or Cobb-Douglas) form which can be linearized by taking logarithms of both sides of the function with the coefficient representing the selling effort elasticity. An alternative to this "double-log" form consists of relating sales to the logarithm of the independent variable, that is the semilogarithmic function. However, the double-log and semilog functions have different implications for optimal allocations. In the former case, the selling effort should be allocated proportional to its elasticity while effort allocation should be proportional to the regression weight in the case of the semilogarithmic function [10].

For response function estimation at the individual customer level however, the output variable data such as physician-level number of prescriptions, is frequently neither continuous nor normally distributed, but is rather Poisson-distributed count data. Therefore, econometricians have modeled prescriptions as a probability function with selling effort (or detailing) as a covariate. To obtain a function with diminishing returns for which an optimal detailing level can be determined, Manchanda and Chintagunta

[11] modeled the Poisson distribution parameter λ (the mean prescription rate, Eq. 2) as an exponential function of a quadratic function of selling effort. Subsequently, Dong *et al.* [12] modeled the impact of selling effort x_{it} with parameters β_{0i} and β_{1i} as shown in Equation (3) in such a way that either a concave or convex or S-shaped relationship may evolve:

$$P_i(y_{it}|\lambda_{it}) = \frac{\lambda_{it}^{y_{it}} \cdot \exp(-\lambda_{it})}{y_{it}!} \quad (i \in I) \quad (2)$$

$$\lambda_{it} = \exp\left(\beta_{0i} + \frac{\beta_{1i}}{1 + x_{it}}\right) \quad (i \in I). \quad (3)$$

Carryover Effects of Selling Effort

With regard to the duration of the effect of personal selling, there is agreement that sales effort has substantial carryover effects [13]. These dynamic effects can be taken into account by either lagged dependent variables, leading to the well-known Koyck model for the case of geometrically decaying memory effects, or by lagged independent or "stock" variables where the effort is cumulated over time but with a certain depreciation rate per period [14].

Dealing with Heterogeneity

Econometric estimation of sales response models calls for fitting a model to historical observations from several time intervals and/or response units. The simplest model assumes that parameter values are the same across cross-sectional units; this is often unrealistic. A simple approach of realizing heterogeneous parameter values for the sales response function is to directly incorporate sources of observed heterogeneity into the model. A more sophisticated approach relies on the estimation of distributions for the response parameter values. This is especially appropriate if longitudinal customer panel data are available, providing a sufficient number of observations for each customer. One could estimate parameter values that follow certain discrete or continuous mixed distributions across the sample of observations. Finite mixture (or latent class) models

allow for the estimation of differing response functions across latent classes or segments [15]. Another option for capturing heterogeneity in parameter values is to derive distributions of parameter estimates applying either a random coefficients approach [16] or a hierarchical Bayes method [11]. Both methods provide posterior estimates per customer.

Dealing with Endogeneity

An unbiased estimation of the parameter values is only possible when the values of the independent variables are randomly chosen. However, the chosen levels of selling effort are often based on the subjective knowledge of managers regarding sales response and are thus nonrandom. This leads to the problem of *endogeneity* of independent variables. Structural approaches to estimation have been proposed to deal with this problem. For example, Manchanda *et al.* [17] propose that the parameter values be estimated with the help of a maximum likelihood approach fitting sales depending on selling effort, as well as selling effort depending on some prior knowledge of the estimated parameter values. However, such a structural approach relies on strong assumptions and it is not clear how meaningful the resulting estimates are when salespeople have not allocated their efforts as assumed. In addition, this approach offers no room to come up with recommendations for improving the allocation of effort which often is the main reason for undertaking the response function estimation in the first place (18, p. 606).

MODELS FOR SALES RESOURCE ALLOCATION AND SALES TERRITORY DESIGN

Sales Resource Allocation Models

Zoltners and Sinha [19] review models that handle basic single-period, single-resource, deterministic resource allocation problem assuming separable sales entities. Only a few models deal with more complicated but realistic problems such as *nonseparable* or interacting sales entities [4,20,21], and

multiple resource-targets; for example, a firm's joint allocation of a team of selling and service reps across its key accounts [22].

A good example for a sales resource allocation model is the influential CALLPLAN by Lodish [4]. This model addressed the question of how a salesperson's time should be allocated between customers and prospects in his/her territory while considering the time required to travel to different subareas of the territory. As shown below, CALLPLAN maximizes the sum of contributions from all customers less the associated travel costs.

Objective function: maximization of profit contribution

$$\sum_{i \in I} \underbrace{g_i \cdot f_i(h_i)}_{\text{profit contribution from sales depending on the calling time}} - \sum_{j \in J} \underbrace{k_j^R \times y_j}_{\text{travel cost multiplied by the number of tours into the subareas}} \Rightarrow \text{Max!} \quad (4)$$

Available working time is constrained to

$$\sum_{i \in I} t_i \cdot h_i + \sum_{j \in J} I_j \cdot y_j \leq T. \quad (5)$$

Number of tours to subarea j must be higher or equal to the maximum number of calls to customer i :

$$h_i \leq y_j \quad (i \in IS_j, j \in J). \quad (6)$$

Lower and upper bound for number of calls:

$$l_j \leq y_j \leq u_j \quad (j \in J). \quad (7)$$

Nonnegativity of number of tours to subarea j :

$$y_j \geq 0 \quad (j \in J). \quad (8)$$

In the above model, the objective (Eq. 4) is to find the optimal allocation of calls h_i across the set of $i \in I$ accounts or account groups that maximizes the sum of profit contributions from calls to accounts (sales $f_i(h_i)$ multiplied with gross margin g_i) less the

total travel costs (number of tours y_j multiplied with average travel cost k_j^R of a tour to subarea $j \in J$). The total time constraint (Eq. 5) ensures that salesperson's time T is not exceeded by the allocated time necessary for calls (h_i weighted with duration of a call t_i summed up over all accounts $i \in I$) and tours to subareas (number of tours y_j multiplied with average duration t_j of a tour to subarea $j \in J$). The constraint with reference to number of trips (Eq. 6) ensures that calls h_i to a particular account cannot exceed the number of trips y_j made to that account's geographic region. Constraint (7) specifies upper and lower bounds on the allocated calls h_i to each account.

As the optimization involving S-shaped response functions is a rather difficult combinatorial problem to solve [23], solutions are obtained using integer programming (see **Formulating Good MILP Models** in the section titled "Optimization Models, Techniques, and Algorithms"). Lodish in fact applies a simpler heuristic in which the sales response function is replaced by its linear concave envelope which provides solutions sufficiently close to the true optimum for most realistic problems. The famous field test at United Airlines by Fudge and Lodish [8] indicated that salespeople using CALLPLAN achieved a significantly higher level of sales increases than the control group. Zoltners and Sinha [19] propose a general modeling approach toward a salesperson call planning system which is conceptually similar to CALLPLAN. Zoltners *et al.* [21] propose an integer programming solution procedure. However, nowadays powerful nonlinear optimization algorithms as implemented in Microsoft's Excel Solver [24] can be more readily used [25,26].

Lastly there have been developments which alter the CALLPLAN model's complicating travel time constraints (Eqs 5 and 6). Specifically, in their COSTA model, Skiera and Albers [7] are able to replace these by a single total selling time constraint, where selling time equals calling time plus travel time, as they directly incorporate selling time into the SCU-level response functions used in their model. This leads to a much simpler optimization structure that can

be solved with standard software such as Microsoft's Excel Solver.

Sales Territory Design

Sales territory design deals with the problem of assigning sets of customers to salespersons. While there are some industries where field sales agents can call on any customer, for example insurance salespeople, most industries work with geographically specialized salesforces, that is salespeople assigned to geographic sales territories. Being assigned his/her own sales territory makes a salesperson feel more responsible and may result in better morale and performance [27]. Geographic sales territories are typically formed by combining SCUs like zip codes or political areas (counties, states, provinces). Then, the sales territory design problem is to determine the combination of SCUs that form each territory.

Hess and Samuels [28] proposed a model-based approach "GEOLINE" to develop *balanced territories*; that is, determine sets of contiguous SCUs which are equalized in terms of workload by minimizing a measure of compactness. "Balancing" is an often sought-after goal to make all salespeople feel they are being treated equitably. Hess and Samuels determined the optimal solution with the help of linear programming (LP) (see **An Introduction to Linear Programming**). However, as an LP's solution is noninteger, and SCUs can only be assigned in their entirety to a territory, GEOLINE works with a rounding procedure that often leads to significant imbalances of workload across territories (of up to 15%). Therefore, Shanker *et al.* [29] as well as Zoltners [30] presented integer programming approaches for the territory alignment task. Lodish [5], on the other hand, focused on a procedure for equalizing the marginal profit contribution across territories. Subsequently, Skiera and Albers [7] showed this is suboptimal as the optimal territories can have different marginal profit contribution values and only have to be equal for SCUs within territories. In another development, Zoltners and Sinha [6] provide a generalization of the earlier models by allowing for any objective function

and achieving almost equality for potential or other balancing criteria through the introduction of lower and upper bounds. However, there remains the question of how to specify the interval between lower and upper bounds. If one tries to minimize travel time then the scarce resource of time becomes more and more irrelevant until there is only one solution satisfying all constraints. However if one relaxes the constraints, then travel time considerations become increasingly important. Consequently, this model would be more helpful to users if it were set up as a multiobjective criteria problem with explicit weights for all criteria.

The model by Zoltners and Sinha [6] also offered some other important enhancements from the viewpoint of implementation. First, territories should not encompass natural boundaries like mountain ranges and rivers that make it nearly impossible to get from one part of the territory to another. This is taken into account by working with actual travel times via a network of major roads. Second, territories should be contiguous. This is ensured by the additional constraint that all SCUs had at least one road connecting to another SCU over which the base location of the salesperson could be reached.

The problem with balancing approaches is that there is only an indirect relationship between profit and territory design. Zoltners and Sinha [27] claim that equal potential increases the utilization of the salesperson's selling time. However, why not try to directly maximize profit contribution when aligning sales territories? This question is addressed by the model COSTA [7] which utilizes a new concept for incorporating travel time effects directly into the sales response function per SCU, depending on the assignment given to a certain salesperson (i.e., territory). This formulation of the sales response function allows for a simultaneous solution of the call planning problem and the assignment of SCUs to territories to maximize overall profit.

Zoltners and Sinha [27] argue that the COSTA approach is too complex and managers implement modified solutions anyway so that the optimality from a profit viewpoint is no longer guaranteed. On the

other hand, substantial progress has been made in reliably estimating sales response functions. And even if the response functions are incorrectly specified, Skiers and Albers [7] show that solutions of COSTA are superior on profit-maximizing grounds to those derived from balancing approaches.

Sales Force Size Decision-Focused Models

In practice, companies often use heuristic or rule-based approaches to setting the size of their sales force, that is the number of salespeople they need over a planning horizon, such as "*same as last year*" or "*pay as you go*" or "*earn-your-way*" strategies that add salespeople as sales grow. Most commonly, sales force sizes are based on a top-down "breakdown" approach under which the total sales force budget (or "costs") is set as a "cost-of-sales" percentage of a sales forecast. This dollar budget divided by the average salesperson salary leads to the selected sales force size. Alternatively, a more data-intensive approach to sales force sizing used by some sales managers is the "bottom-up" *workload buildup* or *activity-based method* [31]. Essentially, these approaches classify customers into segments, set norms for the numbers of sales calls to be made, and fix the number of accounts to be covered in each segment (i.e., the reach). The total workload (sales calls or hours) is then computed and divided by the average rep's call capacity to determine the required sales force size.

The above approaches are likely to produce non-profit-maximizing sales force sizes because first, they do not really focus on profits, and second, they do not fully assess the underlying market sales response functions and resource allocation decisions [32,33].

Recognizing these limitations, a number of normative models for sales force sizing based on sales response functions and marginal analysis have been proposed. More specifically, Dorfman and Steiner's [34] classic theorem establishes that the budgets for marketing instruments can be stated as percentages of profit contribution before marketing costs that equal the respective elasticities. Albers [25] notes that either of the following ratios (Eqs 9 and 10)

provide intuitive insights for managers when concerned with budgeting:

$$\frac{\text{Optimal sales force size (budget)}}{\text{Profit contribution before sales force cost}} = \text{Sales force effort elasticity} \quad (9)$$

$$\frac{\text{Optimal sales force size (budget)}}{\text{Revenue}} = \frac{\text{Sales force effort elasticity}}{\text{Price elasticity}} \quad (10)$$

Integrated Allocation and Territory Design Models

Several models integrate allocation and territory design solutions. One of the earliest was developed by Lodish [5] who extended the CALLPLAN model to incorporate the territory design issue, assuming a fixed sales force size. He maximized profits by equalizing the marginal profit of an additional hour of sales effort across territories with the help of a heuristic. First, he solved the problem of allocating selling time across accounts by assuming one superterritory with the total selling time being equal to the sum of selling times available to all salespersons and applying the CALLPLAN heuristic procedure to determine the optimal number of calls for each account. Then, the decision maker had to reassign accounts step by step intuitively, so that the individual selling time constraints were met and the marginal profit of selling time had become as equal as possible. However, as already noted, the equal marginal profits of selling time achieved were only optimal for the allocation of selling time across accounts or SCUs per territory, but not across territories.

Integrated Sizing and Allocation Models

An early example of this approach is provided by the first stages of Beswick and Cravens' [35] multistage model for sales force management which use sales response functions for small geographic subareas (groups of counties). Subsequently, Lodish [36] argued that developing sales response functions for numerous geographic subareas would be a formidable undertaking in practice. He,

therefore, proposed a decision calculus model for sales force sizing that utilized *product-by-market (customer) segment* sales response functions (where "segments" are mutually exclusive, collectively exhaustive subgroups of the total possible set of customer accounts) and simultaneously optimized product-by-market segment allocations and total sales force size. Lodish *et al.* [9] applied a version of this model at Syntex Laboratories. Later, Lodish [37] reported that Syntex credited this model with increasing their profits by over 20%.

Over 2000 successful applications of similar sales force sizing and resource allocation models have also been claimed by Sinha and Zoltners [13]. According to them, typically, the models applied were nonlinear programming models that utilize product-market segment sales effort response functions and maximize 3- to 5-year profitability for alternative sales force sizes, and product and market allocations.

Empirical Insights, Lessons from Applications. A number of the models described in this section have been applied in practice multiple times mostly by Lodish and his collaborators, and Zoltners, Sinha, and their collaborators at the consulting company ZS Associates Inc. Fortunately, both groups have made efforts over the years to document and publish the results of these model applications and associated experiences [13,27,37]. In general, both groups report that choosing the right model is an art, requiring a good balance between model complexity and ease of understanding, and sensitivity to corporate management goals. Zoltners *et al.* [38] report mature companies boosted their margins by 4.5% when they resized their sales forces and allocated resources better. While 29% of those gains came because the companies corrected the size of their sales forces, 71% of the gains were the results of changes in resource utilization. Based on 1500 successful implementations of sales territory alignments, Zoltners and Sinha [27] state that an improved alignment may provide a profit increase of 2–7%.

CONCLUSIONS

Models for sales force optimization and territory management to date have addressed and even quite successfully resolved some of the traditional strategic, operational, and tactical issues facing sales managers. Some refinements and extensions in solutions in these problem areas are needed but the core ideas are in place. However, the selling environment is rapidly evolving and a number of new sales management challenges are surfacing requiring solutions and offering significant opportunities for new optimization models-based research. These include sales force optimization in a multichannel marketing world where the focus is on customer relationship management and integrated marketing communications.

TWO-STAGE STOCHASTIC PROGRAMMING

Consider the following stochastic programming problem

$$\text{Min}_{x \in \mathcal{X}} \{f(x) := \mathbb{E}[F(x, \xi)]\}. \quad (1)$$

Here $\mathcal{X} \subset \mathbb{R}^n$, ξ is a random vector, whose probability distribution P is supported on set $\Xi \subset \mathbb{R}^d$ and $F: \mathcal{X} \times \Xi \rightarrow \mathbb{R}$. We assume that for every $x \in \mathcal{X}$ the expectation $\mathbb{E}[F(x, \xi)]$, taken with respect to the probability distribution of ξ , is well defined and finite valued. The notation “ $:=$ ” means “equal by definition.”

For example, in a standard formulation of two-stage linear stochastic programming with recourse, Problem (1) has the setting of $\mathcal{X} := \{x \in \mathbb{R}^n : Ax = b, x \geq 0\}$ and $F(x, \xi)$ being equal to the first-stage cost $c^\top x$ plus the optimal value $Q(x, \xi)$ of the second-stage problem

$$\begin{aligned} \text{Min}_{y \in \mathbb{R}^m} \quad & q^\top y \\ \text{s.t.} \quad & Tx + Wy = h, y \geq 0, \end{aligned} \quad (2)$$

depending on the data $\xi = (q, h, T, W)$. By definition, $Q(x, \xi) = +\infty$ if the constraint system of Problem (2) is infeasible, and $Q(x, \xi) = -\infty$ if the Problem (2) is unbounded from below. Of course, in order for $F(x, \xi)$ to have a finite expectation, it is necessary for $F(x, \xi)$ to be finite valued for almost every (a.e.) $\xi \in \Xi$. If for every $x \in \mathcal{X}$, the optimal value $Q(x, \xi) < +\infty$ (i.e., the constraint system has a nonempty set of solutions) for a.e. realization of the random data, then it is said that the two-stage problem has a *relatively complete recourse*.

The expectation $\mathbb{E}[F(x, \xi)]$ is given by the multidimensional integral $\int_{\Xi} F(x, \xi) dP(\xi)$,

which can be evaluated in a closed form, only in rather specific cases. Therefore, a standard approach is to make a discretization of the probability distribution of ξ . That is, a finite number of realizations $\{\xi_1, \dots, \xi_K\}$, called *scenarios*, with respective probabilities $p_1, \dots, p_K$, is constructed. In the case of finite number of scenarios, it follows that $\mathbb{E}[F(x, \xi)] = \sum_{k=1}^K p_k F(x, \xi_k)$, and the two-stage linear stochastic program with recourse can be written as one large linear programming problem:

$$\begin{aligned} \text{Min}_{x, y_1, \dots, y_K} \quad & c^\top x + \sum_{k=1}^K p_k q_k^\top y_k \\ \text{s.t.} \quad & Ax = b, x \geq 0, \\ & T_k x + W_k y_k = h_k, y_k \geq 0, \\ & k = 1, \dots, K, \end{aligned} \quad (3)$$

by making one copy of the second-stage decision vector for every realization (scenario) of the data.

The point is, however, that even a crude discretization of the corresponding probability distribution typically results in an exponential growth of the number of scenarios. Suppose, for example, that components of the d -dimensional random vector ξ are independent of each other and one uses discretization of each marginal distribution with r points. Then the total number of scenarios is $K = r^d$. That is, while the input data (associated with discretization points) grows linearly in d , the number of scenarios grows exponentially. And, indeed, it is shown in Dyer and Stougie [1] that, under the assumption that the stochastic parameters are independently distributed, two-stage linear stochastic programming problems are #P-hard.

This raises the question whether stochastic programming problems can be solved numerically. A possible approach is to consider a moderate number of scenarios and to view our goal as just to design clever algorithms adjusted to a particular structure of the obtained problem. An obvious question with this approach is: “who is going to give us

these scenarios?” Almost surely, the actual future will be different from the future described by a finite number of scenarios. Therefore, only the first-stage decision vector x could be of practical interest in a solution of the two-stage problem (Eq. 3). Note also that in applications, quite often, it does not make much sense to try to solve the corresponding stochastic problem with a high accuracy, say of order 10^{-3} or 10^{-4} , since the involved inaccuracies resulting from inexact modeling, distribution approximations, and so on, could be far greater.

Since deterministic approximations of stochastic programming problems are computationally intractable, one can think about randomization type approaches. We are going to discuss this approach in the next section.

MONTE CARLO SAMPLING METHODS

Suppose that it is possible to generate a random sample $\xi^1, \dots, \xi^N$ of N realizations of the random vector ξ , say by Monte Carlo sampling techniques. We assume now that the sample is Independent Identically Distributed (i.i.d.). Then the expectation function $f(x)$ can be approximated by the corresponding average and hence the “true” problem (Eq. 1) can be approximated by

$$\min_{x \in \mathcal{X}} \left\{ \hat{f}_N(x) := \frac{1}{N} \sum_{j=1}^N F(x, \xi^j) \right\}. \quad (4)$$

By the Law of Large Numbers, we have that for a given $x \in \mathcal{X}$, the sample average $\hat{f}_N(x)$ converges w.p.1 to its expected value $f(x)$ as $N \rightarrow \infty$. Therefore, it is natural to expect that the optimal value and an optimal solution of Problem (4) will converge w.p.1 to their counterparts of the true problem (Eq. 1). And indeed, this can be proved under mild regularity conditions (for a survey of this type of results, we refer the reader to Ref. 2, Section 5.1.1, and references therein).

The above approach to construct Monte Carlo sampling-based approximations of the true problem is a natural one and was used by many authors in slightly different forms, under various names in different contexts. It is difficult to point to an original

introduction of that approach; in stochastic optimization literature, we can mention, for example, Refs 3 and 4, where this approach was called *stochastic counterpart method* and *sample-path optimization*, respectively. Currently it is often referred to as the *sample average approximation* (SAA) method. Once the random sample is generated, the obtained SAA problem can be considered as a stochastic programming problem with N scenarios $\xi^1, \dots, \xi^N$, each taken with equal probability $1/N$. It should be mentioned that the SAA method is not an algorithm, the constructed problem (Eq. 4) still has to be solved by an appropriate numerical procedure.

Unfortunately, for a fixed $x \in \mathcal{X}$, the convergence of the sample average $\hat{f}_N(x)$ to its expected value $f(x)$ is quite slow. By the central limit theorem, we have that $N^{1/2}[\hat{f}_N(x) - f(x)]$ converges in distribution to normal distribution with zero mean and variance equal to the variance $\sigma_x^2 := \mathbb{V}\text{ar}[F(x, \xi)]$, provided that this variance is finite. That is, $\hat{f}_N(x)$ has approximately a normal distribution with mean $f(x)$ and standard deviation $\sigma_x/\sqrt{N}$, and consequently $\hat{f}_N(x)$ converges to $f(x)$ at a (stochastic) rate of $O_p(N^{-1/2})$. In other words, in order to estimate $f(x)$ by its sample average with an accuracy $\varepsilon > 0$, one needs a sample of size $N = O(\varepsilon^{-2})$. Although various techniques, for example, variance reduction techniques and quasi-Monte Carlo methods were developed in simulation literature in order to enhance the accuracy of such estimates (it is far beyond the scope of this article to give a review of these methods, we may refer the interested reader to Refs 5 and 6), it is basically impossible to evaluate multivariate integrals with a high precision. Therefore, there is a little hope that stochastic programming problems can be solved with a high precision. It could be somewhat surprising that the SAA approach turns out to be reasonably efficient for solving certain classes of two-stage stochastic programming problems. This was verified in numerical experiments and is supported by a theory discussed below.

Let us remark that values of the sample average function $\hat{f}_N(x)$ can be computed in two somewhat different, although equivalent, ways. The generated sample $\xi^1, \dots, \xi^N$ can be stored in the computer memory, and called

every time a new value (at a different point x) of the sample average function should be computed. Alternatively, the same sample can be generated by using a common seed number in an employed pseudorandom numbers generator (this is why this approach is called the *common random number generation method*).

The idea of common random number generation is well known in simulation and gives an intuitive explanation why the SAA method may work reasonably well in practical applications. That is, suppose that we want to compare values of the objective function at two points $x_1, x_2 \in \mathcal{X}$. In that case, we are interested in the difference $f(x_1) - f(x_2)$ rather than in the individual values $f(x_1)$ and $f(x_2)$. We can estimate the expectations $f(x_1), f(x_2)$ by their respective sample averages $\hat{f}_N(x_1), \hat{f}_N(x_2)$ using independent samples, both of size N , or the same sample. In both cases, $\mathbb{E}[\hat{f}_N(x_1) - \hat{f}_N(x_2)] = f(x_1) - f(x_2)$, and

$$\begin{aligned} \text{Var}[\hat{f}_N(x_1) - \hat{f}_N(x_2)] \\ = \text{Var}[\hat{f}_N(x_1)] + \text{Var}[\hat{f}_N(x_2)] \\ - 2 \text{Cov}(\hat{f}_N(x_1), \hat{f}_N(x_2)). \end{aligned} \quad (5)$$

Now, in the case of independent samples, $\hat{f}_N(x_1)$ and $\hat{f}_N(x_2)$ are uncorrelated and hence the covariance term in Equation (5) vanishes. On the other hand, in the case of the same sample, the estimators $\hat{f}_N(x_1)$ and $\hat{f}_N(x_2)$ tend to be positively correlated, especially if x_1 and x_2 are close to each other, in which case the variance in Equation (5) becomes smaller.

The basic question of the SAA method is how large should the sample size N be, in order to solve the “true” problem (Eq. 1) with a given precision $\varepsilon > 0$. If the required sample size N is very large, say comparable with the number of scenarios generated by the above discussed discretization procedure, then there is little point in using the SAA approach. Recall that a (feasible) point $\bar{x} \in \mathcal{X}$ is said to be an ε -optimal solution of Problem (1) if $f(\bar{x}) \leq \vartheta^* + \varepsilon$, where $\vartheta^* := \inf_{x \in \mathcal{X}} f(x)$ is the optimal value of the true problem.

By employing large deviations-type probabilistic bounds, it is possible to give an estimate of the sample size N such that any ε' optimal solution, with $\varepsilon' \in (0, \varepsilon)$, of the SAA problem gives an ε optimal solution of the

true problem (Eq. 1) with a probability of at least $1 - \alpha$, where $\alpha \in (0, 1)$ is a small number (significance level). That is, by solving the SAA problem with precision, say, $\varepsilon' = \varepsilon/2$, we are guaranteed with confidence of say, 99% that we solve the true problem with precision ε . Under certain regularity conditions, the following estimate of the sample size guarantees this property [2,7]; see also Ref. 8, Section 5.3.2 for a discussion of such estimates:

$$N = O(1) \left(\frac{DL}{\varepsilon} \right)^2 \left[n \log \left(\frac{DL}{\varepsilon} \right) + \log \left(\frac{1}{\alpha} \right) \right]. \quad (6)$$

Here $O(1)$ denotes a generic constant independent of the data, n is the dimension of the decision vector x , D is the diameter of the feasible set $\mathcal{X}$ and L is Lipschitz constant of $F(\cdot, \xi)$ on $\mathcal{X}$ for all $\xi \in \Xi$. Of course, the estimate (Eq. 6) makes sense only if constants D and L are finite.

A discussion of the above estimate is now in order. In a sense, the bound (Eq. 6) gives an estimate of complexity of solving the true problem; the larger the sample size N , the more time consuming it is to solve the corresponding SAA problem. In case of linear two-stage programming, the computational effort in solving the SAA problems is more or less proportional to N (i.e., this is an empirical observation). Formula (6) suggests that the sample size N is “almost” proportional to ε^{-2} (the additional dependence on $\log(\varepsilon^{-1})$ is practically constant). Such dependence of the sample size on ε is typical for Monte Carlo-type methods and cannot be significantly changed unless the considered class of problems has a specific structure. The significance level constant α is under the logarithm sign. This means that increasing confidence, say, from 99% to 99.9% does not significantly change the sample size estimate.

The above discussion suggests that the true problem (Eq. 1) can be solved by the SAA method in a reasonable time with a reasonable accuracy provided that the following conditions are satisfied: (i) the required sample size is manageable; (ii) it is possible to solve the constructed SAA problem with a reasonable efficiency. From this point of view, the number of scenarios of the true problem

(i.e., cardinality of the support Ξ of the distribution of ξ) is irrelevant and can be infinite. The condition (ii) holds in the case of two-stage linear stochastic programming with recourse. The condition (i) holds if for every $x \in \mathcal{X}$ variability of $F(x, \xi)$ is “not too large.” In particular, $F(x, \xi)$ should be finite valued for a.e. realization of ξ . In case of two-stage stochastic programming, this means that the recourse should be relatively complete and the second-stage problem should be bounded from below.

It should be mentioned that Formula (6) has a theoretical value and is not useful for practical applications. This is because it typically gives an estimate of the required sample size far bigger than is actually needed. In the next section, we discuss a practical way of evaluating a given solution.

VALIDATION ANALYSIS

Suppose that we are given a feasible point $\bar{x} \in \mathcal{X}$ as a candidate for an optimal solution of the true problem. For example, $\bar{x}$ can be an output of a run of the corresponding SAA problem. In this section, we discuss a way to evaluate the quality of this candidate solution by estimating the optimality gap $f(\bar{x}) - \vartheta^*$ (recall that ϑ^* denotes the optimal value of the true problem). Since $\bar{x} \in \mathcal{X}$ is feasible, we have, of course that $f(\bar{x}) \geq \vartheta^*$. The following statistical procedure was developed by Mak *et al.* [9].

We can estimate $f(\bar{x})$ by the sample average $\hat{f}_{N'}(\bar{x})$, based on an i.i.d. sample of size N' . Note that since the point $\bar{x}$ is fixed, there is no need to solve the corresponding stochastic problem and hence one can use a large sample. Note also that the employed sample should be independent of the sample used in construction of the point $\bar{x}$. Together with $\hat{f}_{N'}(\bar{x})$, one can compute the sample estimate $\hat{\sigma}_{N'}^2(\bar{x})$ of the variance $\text{Var}[\hat{f}_{N'}(\bar{x})]$, and hence to construct the following $100(1 - \alpha)\%$ confidence upper bound

$$U_{N'}(\bar{x}) := \hat{f}_{N'}(\bar{x}) + z_\alpha \hat{\sigma}_{N'}(\bar{x}), \quad (7)$$

for $f(\bar{x})$ [here z_α is the $(1 - \alpha)$ -quantile of the standard normal distribution].

In order to construct a lower bound for ϑ^* , we proceed as follows. Denote by $\hat{\vartheta}_N$, the

optimal value of the SAA problem (Eq. 4). Note that $\hat{\vartheta}_N$ is random, since it is a function of the sample used in construction of the SAA problem. It is not difficult to show that $\vartheta^* \geq \mathbb{E}[\hat{\vartheta}_N]$, that is, $\mathbb{E}[\hat{\vartheta}_N]$ gives a lower bound for the true optimal value ϑ^* . The expectation $\mathbb{E}[\hat{\vartheta}_N]$ can be estimated by averaging. That is, one can solve M times SAA problems based on independently generated samples each of size N . Let $\hat{\vartheta}_N^1, \dots, \hat{\vartheta}_N^M$ be the computed optimal values of these SAA problems. Then,

$$\bar{v}_{N,M} := \frac{1}{M} \sum_{m=1}^M \hat{\vartheta}_N^m \quad (8)$$

is an unbiased estimator of $\mathbb{E}[\hat{\vartheta}_N]$. Since the samples, and hence $\hat{\vartheta}_N^1, \dots, \hat{\vartheta}_N^M$, are independent and have the same distribution, we have that $\text{Var}[\bar{v}_{N,M}] = M^{-1} \text{Var}[\hat{\vartheta}_N]$, and hence we can estimate variance of $\bar{v}_{N,M}$ by

$$\hat{\sigma}_{N,M}^2 := \frac{1}{M(M-1)} \sum_{m=1}^M (\hat{\vartheta}_N^m - \bar{v}_{N,M})^2. \quad (9)$$

Consequently,

$$L_{N,M} := \bar{v}_{N,M} - t_{\alpha, M-1} \hat{\sigma}_{N,M} \quad (10)$$

can be used as an approximate $100(1 - \alpha)\%$ confidence lower bound for the expectation $\mathbb{E}[\hat{\vartheta}_N]$. Note that the sample size M does not need to be large. Already with, say $M = 5$, one often can get an idea about variability of $\hat{\vartheta}_N$. The α -critical value $t_{\alpha, M-1}$, of t -distribution with $M - 1$ degrees of freedom is slightly bigger than the corresponding standard normal critical value z_α , and is used in order to compensate for the approximate nature of the lower confidence bound $L_{N,M}$, when M is small.

We have

$$\mathbb{E}[\hat{f}_{N'}(\bar{x}) - \bar{v}_{N,M}] = f(\bar{x}) - \mathbb{E}[\hat{\vartheta}_N] \geq f(\bar{x}) - \vartheta^*,$$

and hence

$$\hat{f}_{N'}(\bar{x}) - \bar{v}_{N,M} + z_\alpha \sqrt{\hat{\sigma}_{N'}^2(\bar{x}) + \hat{\sigma}_{N,M}^2} \quad (11)$$

provides a $100(1 - \alpha)\%$ confidence upper bound for the optimality gap. This upper bound is somewhat “conservative” since

$\vartheta^* \geq \mathbb{E}[\hat{\vartheta}_N]$, that is, $\bar{v}_{N,M}$ is a downward biased estimate of ϑ^* (see Ref. 2, Section 5.6.1, for a discussion of this bias problem and Ref. 10 for some ideas on reducing the computational burden of solving M problems).

CHANCE-CONSTRAINED PROBLEMS

Consider the following chance-constrained problem

$$\min_{x \in \mathcal{X}} f(x) \text{ subject to } p(x) \leq \alpha, \quad (12)$$

where $\alpha \in (0, 1)$ is a given significance level, $\mathcal{X} \subset \mathbb{R}^n$ is a closed set, $f: \mathbb{R}^n \rightarrow \mathbb{R}$ and $C: \mathcal{X} \times \Xi \rightarrow \mathbb{R}$, and $p(x) := \text{Prob}\{C(x, \xi) > 0\}$. The chance (probabilistic) constraint $p(x) \leq \alpha$ makes sure that the constraint $C(x, \xi) \leq 0$, depending on the random vector $\xi \in \Xi$, holds with probability at least $1 - \alpha$. For a general discussion of chance-constrained problems, we refer to Prékopa [11].

We can write the probability $p(x)$ in the form of the expectation,

$$p(x) = \mathbb{E}[\mathbf{1}_{(0, \infty)}(C(x, \xi))],$$

where $\mathbf{1}_{(0, \infty)}(\cdot)$ is the indicator function of $(0, \infty)$, that is, $\mathbf{1}_{(0, \infty)}(t) = 1$ if $t > 0$, and $\mathbf{1}_{(0, \infty)}(t) = 0$ if $t \leq 0$. Consequently $p(x)$ can be estimated by the corresponding sample average function

$$\hat{p}_N(x) = N^{-1} \sum_{j=1}^N \mathbf{1}_{(0, \infty)}(C(x, \xi^j)). \quad (13)$$

That is, $\hat{p}_N(x)$ is equal to the proportion of times that $C(x, \xi^j) > 0$, $j = 1, \dots, N$. An associated SAA problem can be written as

$$\min_{x \in \mathcal{X}} f(x) \text{ subject to } \hat{p}_N(x) \leq \gamma. \quad (14)$$

Note that we allow here for the significance level $\gamma \in [0, 1)$ of the SAA problem to be different from the significance level α of the true problem (Eq. 12).

As before, once the random sample is generated, the SAA problem can be viewed as a chance-constrained problem with scenarios $\xi^1, \dots, \xi^N$, each taken with probability $1/N$. For $\gamma > 0$, Problem (14) could be a

difficult combinatorial problem. Therefore, from a computational point of view it is advantageous to take $\gamma = 0$, in which case Problem (14) can be written as

$$\min_{x \in \mathcal{X}} f(x) \text{ subject to } C(x, \xi^j) \leq 0, j = 1, \dots, N. \quad (15)$$

If the functions $f(\cdot)$, $C(\cdot, \xi)$, $\xi \in \Xi$, are convex (linear), then Problem (15) is a convex (linear) programming problem and could be solved by efficient optimization procedures, provided that N is not too large.

Denote by $B(\cdot; \alpha, N)$, the cumulative distribution function of binomial distribution with probability of success α and number of trials N , that is,

$$B(k; \alpha, N) = \sum_{i=0}^k \binom{N}{i} \alpha^i (1-\alpha)^{N-i}, \quad k=0, \dots, N.$$

It is shown by Campi and Garatti [12], building on the work of Calafiore and Campi [13], that in the convex case under mild regularity conditions, if the sample size N satisfies the condition $B(n-1; \alpha, N) \leq \beta$, then with probability of at least $1 - \beta$, an optimal solution $\bar{x}$ of Problem (15) is a *feasible* point of the true problem (Eq. 12). This leads to an estimate of the sample size of order $N = O(\alpha^{-1})$, which guarantees with the specified confidence $1 - \beta$, that by solving Problem (15), one computes a feasible point of the true problem.

The above result, however, does not say much about optimality of the point $\bar{x}$. And, indeed, as the sample size N increases, the feasible set of Problem (15) will shrink to the set defined by constraints $C(x, \xi) \leq 0$ for all $\xi \in \Xi$, and hence eventually, the feasible set of Problem (15) becomes smaller than the feasible set of the true problem (Eq. 12). An alternative approach will be to take $\gamma = \alpha$. In that case, under mild regularity conditions, the optimal value and optimal solutions of the SAA problem (Eq. 14) will converge w.p.1 to their counterparts of the true problem (Eq. 12). For an approach to solving a certain class of chance-constrained SAA problems, we refer to the recent paper [14]. It is also possible to construct statistical upper and lower bounds for the optimal

value of the true problem (Eq. 12), by solving SAA problems of the form (Eq. 14) with $\gamma \in [0, 1]$ [15]. For some numerical experiments with various sampling-based approaches to chance-constrained problems see Ref. 16.

CONCLUDING REMARKS

For *convex* stochastic problems, an alternative to the SAA approach is the stochastic approximation (SA) method going back to Robbins and Monro [17]. The classical SA algorithm generates iterations by the formula

$$x_{j+1} = \Pi_{\mathcal{X}}(x_j - \gamma_j G(x_j, \xi^j)), \quad j = 1, \dots, \quad (16)$$

where $G(x, \xi) \in \partial_x F(x, \xi)$ is a subgradient of $F(x, \xi)$, $\Pi_{\mathcal{X}}$ is the metric projection onto the set $\mathcal{X}$, and $\gamma_j > 0$ are chosen step sizes. We may refer to Ref. 18 for a discussion of convergence properties of this method. The standard choice of the step sizes is $\gamma_j = \theta/j$ for some constant $\theta > 0$. For an *optimal* choice of the constant θ , the estimates of rates of convergence of this method are similar to the respective estimates of the SAA method. However, the method is very sensitive to the choice of the constant θ and often does not work well in practice (see, e.g., a simple example in Ref. 19, p. 1578, where it is demonstrated that a wrong choice of θ can result in a disastrously slow rate of convergence). It is somewhat surprising that a robust version of the SA algorithm, taking its origins in the mirror descent method of Nemirovski and Yudin [20], can significantly outperform SAA based algorithms for certain classes of convex stochastic problems [19].

So far we discussed static (two-stage and chance-constrained) stochastic programming problems. In principle, it is possible to extend the SAA methodology (including construction of upper and lower statistical bounds) to dynamic (multistage) stochastic programming by employing randomly generated scenarios. It should be noted, however, that the number of scenarios required to solve the true problem with a given accuracy $\varepsilon > 0$ grows exponentially with increase in the number of stages [21,22]. This makes

the SAA method practically inapplicable to multistage stochastic programming with a number of stages, say $T \geq 4$, unless the considered problems have a specific structure.

SCENARIO GENERATION

WERNER RÖMISCH
Humboldt-University Berlin,
Institute of Mathematics,
Berlin, Germany

Many stochastic programming models may be rewritten into the form

$$\min \left\{ \int_{\Xi} f_0(x, \xi) P(d\xi) : x \in X, \right. \\ \left. \int_{\Xi} f_k(x, \xi) P(d\xi) \leq 0, k = 1, \dots, K \right\}, \quad (1)$$

where X is a closed subset of $\mathbb{R}^m$, Ξ a closed subset of $\mathbb{R}^d$, the functions f_k map from $\mathbb{R}^m \times \Xi$ to the extended real numbers $\mathbb{R}$ for $k = 0, \dots, K$, and P is a probability distribution on Ξ . The set X is used to describe all constraints not depending on P , and the set Ξ to contain the support of P . The integrands f_k are assumed to be lower semicontinuous jointly in (x, ξ) implying that all integrals in problem (1) are well defined (although possibly infinite).

Classical examples are *linear two-stage stochastic programs* and *optimization models with probabilistic constraints*. Linear two-stage models appear for $K := 0$ and f_0 having the representation

$$f_0(x, \xi) := \langle c(\xi), x \rangle + \inf \{ \langle q(\xi), y \rangle : W(\xi)y \\ = h(\xi) - T(\xi)x, y \geq 0 \} \quad (2)$$

by means of the infimum of a second stage linear program where some of the coefficients are affine functions of the d -dimensional random vector ξ and the variable x is the first stage decision. Models with probabilistic constraints appear, for example, for $K = 1$, $f_0(x, \xi) = \langle c, x \rangle$ and

$$f_1(x, \xi) = p - \mathbf{1}_{\{\xi \in \Xi: T(\xi)x \geq h(\xi)\}}(\xi),$$

where $\mathbf{1}_B$ denotes the characteristic function of a set B in $\mathbb{R}^d$ and $p \in (0, 1)$ is a probability level (see also **Models and Basic Properties**).

APPROXIMATION

Stability results for problem (1) with respect to approximations Q of the original probability distribution P (see Ref. 1 for a survey) state that infimal values $v(P)$ and $v(Q)$ and solution sets $S(P)$ and $S(Q)$ of the stochastic programs (1) with distributions P and Q , respectively, get close if the (uniform) distance of P and Q

$$d_{\mathcal{F}}(P, Q) = \sup_{f \in \mathcal{F}} \left| \int_{\Xi} f(\xi) P(d\xi) - \int_{\Xi} f(\xi) Q(d\xi) \right|, \quad (3)$$

with $\mathcal{F} = \{f_k(x, \cdot) : x \in X, k = 0, \dots, K\}$ gets small, the set X is compact, the objective function $x \mapsto \int_{\Xi} f_0(x, \xi) P(d\xi)$ is Lipschitz continuous on X and a metric regularity condition for the constraint set is satisfied. The latter two conditions are only needed if $K \geq 1$. As we have seen before, typical integrands f in stochastic programs are nondifferentiable or even discontinuous. (For simplicity, we assume here that all integrals in problem (1) are finite for every $x \in X$ and for the probability distribution P and its approximations Q .)

The most important way to approximate P consists in utilizing discrete probability measures Q_n having finite support

$$\text{supp}(Q_n) = \{\xi^1, \dots, \xi^n\} \subset \Xi,$$

for some $n \in \mathbb{N}$. The elements of $\text{supp}(Q_n)$ are often called *scenarios*. When replacing P by Q_n in problem (1), the (multivariate) integrals in problem (1) reduce to weighted sums and one obtains

$$\min \left\{ \sum_{i=1}^n q_i f_0(x, \xi^i) : x \in X, \right. \\ \left. \sum_{i=1}^n q_i f_k(x, \xi^i) \leq 0, k = 1, \dots, K \right\}, \quad (4)$$

where $q_i = Q_n(\{\xi^i\}) > 0$ is the probability that scenario ξ^i occurs ($i = 1, \dots, n$). Clearly,

we have $\sum_{i=1}^n q_i = 1$. The structure of the approximate stochastic programming problem (4) is very close to a standard (linear, nonlinear, and integer) optimization model. The only remaining difficulty consists in the need of many evaluations of the functions f_k at the pairs (x, ξ^i) , $i = 1, \dots, n$, if the number n of scenarios gets large. But, large n are often unavoidable when recalling numerical integration even in dimension $d = 1$ and all the more for large d as in many applied stochastic programming models, in production, energy, transportation, and finance. According to our stability considerations, the number n , the scenarios $\xi^i \in \Xi$ and their probabilities q_i for $i = 1, \dots, n$ should be selected such that for given $\varepsilon > 0$ the (absolute) error satisfies

$$e(Q_n) := \sup_{f \in \mathcal{F}} \left| \int_{\Xi} f(\xi) P(d\xi) - \sum_{i=1}^n q_i f(\xi^i) \right| \leq \varepsilon, \quad (5)$$

with $\mathcal{F}$ defined earlier. Another and more feasible condition consists in utilizing the relative error such that given $\varepsilon \in [0, 1]$, we look for a probability measure Q_n such that

$$e(Q_n) \leq \varepsilon e(\bar{Q}_1), \quad (6)$$

where the measure $\bar{Q}_1$ consists of only one distinguished scenario $\bar{\xi}$ with probability 1. A more advanced requirement consists in looking for Q_n with the smallest number $n = n_{\min}(\varepsilon, Q_n) \in \mathbb{N}$ of scenarios such that Equation (6) holds. Sometimes even $Q_0 = 0$ is considered in the literature [2] and, thus, the criterion (6) is of the form

$$e(Q_n) \leq \varepsilon \sup_{f \in \mathcal{F}} \left| \int_{\Xi} f(\xi) P(d\xi) \right|. \quad (7)$$

The behavior of $e(Q_n)$ with respect to $n \in \mathbb{N}$ and of $n_{\min}(\varepsilon, Q_n)$ with respect to ε is of considerable interest. In both cases, the dependence on the dimension d of P is crucial, too.

It is not surprising that the behavior of the two quantities depends heavily on the set $\mathcal{F}$ of integrands as well as on the probability distribution P . Since the set $\mathcal{F}$ in its present form is not very convenient to handle,

it might be an alternative to enlarge $\mathcal{F}$ in estimates (5–7). But, one has to be careful in this process as is shown next.

If $\mathcal{F}$ is the unit ball in the Banach space $\text{Lip}(\mathbb{R}^d)$ of Lipschitz continuous functions on $\Xi = \mathbb{R}^d$ and if $q_i = \frac{1}{n}$, $i = 1, \dots, n$, one obtains

$$e(Q_n) = Cn^{-\frac{1}{d}}, \quad (8)$$

for some constant C depending only on P under the weak assumptions that P is not singular with respect to the Lebesgue measure on $\mathbb{R}^d$ and that the moment $\int_{\mathbb{R}^d} \|\xi\|^{1+\delta} P(d\xi)$ is finite for some $\delta > 0$ [3, Theorem 6.2].

The rate (8) suggests that the unit ball in $\text{Lip}(\mathbb{R}^d)$ is too large and one should look for function classes $\mathcal{F}$ satisfying more restrictive conditions. One possibility is offered by the classical Koksma–Hlawka inequality [4,5]. It states for an integrand f on $\Xi = [0, 1]^d$ that is of bounded variation $V(f)$ in the sense of Hardy and Krause that the estimate

$$\left| \int_{\Xi} f(\xi) d\xi - \sum_{i=1}^n q_i f(\xi^i) \right| \leq V(f) \alpha^*(\lambda^d, Q_n), \quad (9)$$

holds with $q_i = \frac{1}{n}$, $i = 1, \dots, n$ and with the so-called *star-discrepancy* α^* defined by

$$\alpha^*(P, Q) = \sup_{\xi \in [0, 1]^d} |P([0, \xi]) - Q([0, \xi])|,$$

where $[0, \xi] = \times_{i=1}^d [0, \xi_i]$. For problem (1) with $K = 0$ and $\Xi = [0, 1]^d$, the Koksma–Hlawka inequality 9 leads to the estimate

$$\begin{aligned} e(Q_n) &\leq \sup_{f \in \mathcal{F}} V(f) \alpha^*(P, Q_n) \\ &= \sup_{x \in X} V(f_0(x, \cdot)) \alpha^*(P, Q_n). \end{aligned}$$

If $P = \lambda^d$ is the uniform distribution on $\Xi = [0, 1]^d$ and $q_i = \frac{1}{n}$, $i = 1, \dots, n$, it is known [4, Chapter 3.1] that there exist sequences $(\xi^i)_{i \in \mathbb{N}}$ with

$$\alpha^*(P, Q_n) = O(n^{-1}(\log n)^d). \quad (10)$$

Hence, compared with Equation (8), a much better convergence rate for $e(Q_n)$ can be

obtained under stronger assumptions on $\mathcal{F}$. Initiated by the pioneering work of Sloan and Woźniakowski [2], the convergence rate is further improved if the set $\mathcal{F}$ is bounded in the weighted tensor product space

$$W_2^{(1,\dots,1)}([0,1]^d) = \bigotimes_{i=1}^d W_2^1([0,1]), \quad (11)$$

where $W_2^1([0,1])$ is the Sobolev space of absolutely continuous real functions whose first derivatives belong to $L_2([0,1])$. The space (11) contains all real functions f on $[0,1]^d$, for which all mixed partial derivatives $\frac{\partial^{|u|}}{\partial \xi_u} f(\xi_u, 1)$ exist for almost every $\xi_u \in [0,1]^{|u|}$ and $u \subseteq D = \{1, \dots, d\}$ and for which the weighted norm

$$\|f\|_{d,\gamma} = \left(\sum_{u \subseteq D} \prod_{j \in u} \gamma_j^{-1} \int_{[0,1]^{|u|}} \left| \frac{\partial^{|u|}}{\partial \xi_u} f(\xi_u, 1) \right|^2 d\xi_u \right)^{\frac{1}{2}}$$

is finite. Here, we denote by $|u|$ the cardinality of $u \subseteq D$, and by $\xi_u \in [0,1]^{|u|}$, the vector containing the components of $\xi \in [0,1]^d$ whose indices are in u . The weights (γ_j) are positive and monotonically decreasing with $\gamma_1 = 1 = \prod_{j \in \emptyset} \gamma_j^{-1}$.

By utilizing the weighted Koksma–Hlawka inequality,

$$\left| \int_{\Xi} f(\xi) d\xi - \frac{1}{n} \sum_{i=1}^n f(\xi^i) \right| \leq \text{disc}_{\gamma}((\xi^i)) \|f\|_{d,\gamma}$$

with $\text{disc}(\xi) = \prod_{j=1}^d \xi_j - n^{-1} \sum_{\xi^i \in [0,\xi]} i$ and the weighted L_2 -star-discrepancy

$$\text{disc}_{\gamma}((\xi^i)) = \left(\sum_{\emptyset \neq u \subseteq D} \prod_{j \in u} \gamma_j \int_{[0,1]^{|u|}} \text{disc}^2(\xi_u, 1) d\xi_u \right)^{\frac{1}{2}}$$

instead of $\alpha^*(\lambda^d, Q_n)$ in Equation (9), it became possible in Refs 2 and 6 to prove the existence of a sequence $(\xi^i)_{i \in \mathbb{N}}$ such that for any $\delta > 0$ the estimate

$$e(Q_n) \leq C(\delta) n^{-1+\delta} \quad (12)$$

holds, where $C(\delta)$ is independent of n and d if the weights (γ_j) satisfy the condition $\sup_d \sum_{j=1}^d \gamma_j < \infty$. While the results in Refs 2 and 6 were nonconstructive, it is reported in Ref. 7 that certain shifted lattice rules attain the optimal order (12) of convergence.

SCENARIO GENERATION TECHNIQUES

We briefly discuss here about four different scenario generation techniques for stochastic programs without nonanticipativity constraints:

1. Monte Carlo simulation methods,
2. Quasi–Monte Carlo (QMC) methods,
3. Quadrature rules using sparse grids,
4. Optimal quantization (or discretization) of probability measures.

Monte Carlo Simulation Methods

Monte Carlo methods are based on drawing independent identically distributed (iid) Ξ -valued random samples $\xi^1(\cdot), \dots, \xi^n(\cdot), \dots$ [defined on some probability space $(\Omega, \mathcal{A}, \mathbb{P})$] from an underlying probability distribution P (on Ξ) and on using the law of large numbers to obtain

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{i=1}^n f(\xi^i(\omega)) = \int_{\Xi} f(\xi) P(d\xi) \quad \mathbb{P}\text{-almost surely}$$

for every real continuous and bounded function f on Ξ . Practically, iid samples are approximately obtained by pseudorandom number generators as uniform samples in $[0,1]^d$ and later transformed to more general sets and distributions. This technique may be applied, for example, to certain time series models (calibrated to the available statistical data) or to the statistical data directly. For details, refer to the article **Sampling Methods** in this encyclopedia.

Quasi–Monte Carlo Methods

The basic idea of QMC methods is to replace random samples in Monte Carlo methods by

deterministic points that are *uniformly distributed* in $[0, 1]^d$. One possibility for defining the latter property for a sequence $(\xi^i)_{i \in \mathbb{N}}$ is to require that

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{i=1}^n f(\xi^i) = \int_{[0,1]^d} f(\xi) d(\xi) \quad (13)$$

holds for all real continuous functions f on $[0, 1]^d$. Basic references for QMC methods are Refs 4 and 8. With $P = \lambda^d$ (the d -dimensional Lebesgue measure) and $Q = Q_n$ denoting the probability measure with support $\text{supp}(Q_n) = \{\xi^1, \dots, \xi^n\}$ and with identical probabilities $\frac{1}{n}$ for all atoms, the estimate (9) highlights the importance of the star-discrepancy of the point set $\{\xi^1, \dots, \xi^n\}$

$$\text{disc}^*(\xi^1, \dots, \xi^n) := \alpha^*(\lambda^d, Q_n)$$

in this respect. Hence, one should look for *low discrepancy sequences*, that is, sequences $(\xi^i)_{i \in \mathbb{N}}$ such that $\text{disc}^*(\xi^1, \dots, \xi^n)$ is low for all n . Such sequences have the property

$$\frac{1}{2} n^{-1} \leq \text{disc}^*(\xi^1, \dots, \xi^n) = O(n^{-1}(\log n)^d).$$

In particular, we refer to the sequences discussed in Refs 8 (Section 5.4) and 9, namely, *Faure, Sobol, and Niederreiter sequences*. The latter are special cases of so-called (t, m, d) -sequences which in turn are based on (t, m, d) -nets [4, Chapter 4]. The latter (t, m, d) -nets and lattices [4, Chapter 5; 8, Section 5.3] represent (finite) *low discrepancy point sets* and are, presently, the most important sources for QMC methods.

If $G : [0, 1]^d \rightarrow \Xi$, $\Xi \subseteq \mathbb{R}^d$, is almost everywhere continuous, then Equation (13) means that the sequence (Q_n) converges weakly to λ^d and the continuous mapping theorem [10, Chapter 5] implies that the sequence $(Q_n G^{-1})$ converges weakly to $\lambda^d G^{-1}$. This fact allows to apply QMC methods to many situations in stochastic programming.

Quadrature Rules Using Sparse Grids

Again, we consider first the unit cube $[0, 1]^d$ in $\mathbb{R}^d$. Let nested sets of grids in $[0, 1]$ be given

$$\Xi^i = \{\xi_1^i, \dots, \xi_{m_i}^i\} \subset \Xi^{i+1} \subset [0, 1] \quad (i \in \mathbb{N}),$$

for example, the dyadic grid $\Xi^i = \{\frac{j}{2^i} : j = 0, 1, \dots, 2^i\}$. Then, the point set suggested by Smolyak [11]

$$H(q, d) := \bigcup_{\sum_{j=1}^d i_j = q} \Xi^{i_1} \times \dots \times \Xi^{i_d} \quad (14)$$

is called a *sparse grid* in $[0, 1]^d$ and points in $H(q, d)$ are also called *hyperbolic cross points*. In case of dyadic grids in $[0, 1]$, $H(q, d)$ consists of all d -dimensional dyadic grids with product of mesh size given by $\frac{1}{2^q}$ [12].

The corresponding tensor product quadrature rules for $q \geq d$ on $[0, 1]^d$ with respect to the Lebesgue measure λ^d are of the form

$$\begin{aligned} I(q, d) = & \sum_{q-d+1 \leq |\mathbf{i}| \leq q} (-1)^{q-|\mathbf{i}|} \binom{d-1}{q-|\mathbf{i}|} \\ & \times \sum_{j_1=1}^{m_{i_1}} \dots \sum_{j_d=1}^{m_{i_d}} f(\xi_{j_1}^{i_1}, \dots, \xi_{j_d}^{i_d}) \prod_{l=1}^d a_{j_l}^{i_l}, \end{aligned} \quad (15)$$

where $|\mathbf{i}| = \sum_{j=1}^d i_j$ and the coefficients $a_{j_l}^{i_l}$ ($j = 1, \dots, m_i$, $i = 1, \dots, d$) are weights of one-dimensional quadrature rules. Even if the one-dimensional weights are positive, some of the weights in Equation (15) are negative. Hence, an interpretation as scenario-based (discrete) probability measure is no longer possible. We note that the results in Ref. 13 (as extension of Ref. 2, see Section 1) apply to such tensor product quadrature rules.

Optimal Quantization of Probability Measures

Let D be a metric distance of probability measures on $\mathbb{R}^d$, for example, the Fortet–Mourier metric ζ_r of order r (to be used in the next section), the minimal L_r -metric ℓ_r used in Ref. 3 or some other metric [14] such that the underlying stochastic program behaves stable with respect to D . Furthermore, let P be a given probability distribution on $\mathbb{R}^d$. We are looking for a discrete probability measure Q_n with support $\text{supp}(Q_n) = \{\xi^1, \dots, \xi^n\}$,

$Q_n(\{\xi^i\}) = p_i, i = 1, \dots, n$, such that it is the best approximation to P in the sense

$$\begin{aligned} D(P, Q_n) &= \min\{D(P, Q) : |\text{supp}(Q)| \\ &= n, Q(\mathbb{R}^d) = 1\}. \end{aligned} \quad (16)$$

In many cases, the distance $D(P, Q)$ may be reformulated as a real function Φ defined on $[0, 1]^n \times \mathbb{R}^{dn}$. It attains its global minimum subject to the standard simplex constraint for the first n variables at $(p_1, \dots, p_n; \xi^1, \dots, \xi^n)$. Unfortunately, the function Φ is nonconvex and often nondifferentiable, hence, minimizing it is not an easy task.

We refer to Refs 15–17 for developing algorithmic procedures for minimizing Φ globally, for example, stochastic gradient algorithms, stochastic approximation methods, and stochastic branch-and-bound techniques.

The methodology of optimal quantization may be extended to multistage stochastic programs by incorporating constraints describing the tree structure [15,16].

SCENARIO REDUCTION

Let P be a probability measure on $\mathbb{R}^d$ having N scenarios ξ^i with probabilities $p_i, i = 1, \dots, N$. We consider P as approximation of the original probability distribution of a stochastic program that has to be solved computationally. Owing to running time requirements N might be too large and we have to look for an approximation Q_n of P whose support consists of only $n < N$ scenarios out of $\{\xi^1, \dots, \xi^N\}$. Then two questions arise: (i) Which of the N scenarios should be deleted and (ii) which probabilities should be assigned to the n remaining scenarios?

We review below the stability-based approach for (optimal) scenario reduction developed in the articles [18–20]. It is based on considering the distance $d_{\mathcal{F}}(P, Q_n)$ (see Eq. 3 in the section titled “Approximation”) and in determining Q_n as best approximation of P with respect to $d_{\mathcal{F}}$ among all probability measures whose supports consist of n scenarios out of $\{\xi^1, \dots, \xi^N\}$. An equivalent formulation of this best approximation problem is as follows: Let Q_J denote a probability measure

on $\mathbb{R}^d$ with $\text{supp}(Q_J) = \{\xi^i : i \in I \setminus J\}$ for some index set $J \subset I := \{1, \dots, N\}$ and let q_i be the probability of the scenario indexed by i for every $i \in I \setminus J$. Then the minimization problem

$$\begin{aligned} \min \Big\{ d_{\mathcal{F}}(P, Q_J) : J \subset I, |J| = N - n, \\ q_i \geq 0, i \in I \setminus J, \sum_{i \in I \setminus J} q_i = 1 \Big\} \end{aligned} \quad (17)$$

determines some index set J_n and weights $\bar{q}_i \in [0, 1]$ such that the probability measure $Q_n := Q_{J_n}$ with scenarios ξ^i and probabilities $\bar{q}_i$ for $i \in I \setminus J_n$ solves the best approximation problem. The formulation (17) of optimal scenario reduction leads immediately to a decomposition into an *inner* and an *outer* minimization problem, namely,

$$\begin{aligned} \min_J \Big\{ \inf_q \Big\{ d_{\mathcal{F}}(P, Q_J) : q_i \geq 0, i \in I \setminus J, \\ \sum_{i \in I \setminus J} q_i = 1 \Big\} : J \subset I, |J| = N - n \Big\}. \end{aligned} \quad (18)$$

In particular, the approach becomes powerful if solutions and the infimum $D_J(\mathcal{F}, P)$ of the inner problem may be determined explicitly for any index set $\emptyset \neq J \subset I$. In that case, the *optimal redistribution* of the N probabilities $p_i, i \in I$, to the n scenarios indexed by $I \setminus J$ is known and it remains to solve the outer (combinatorial) optimization problem

$$\min\{D_J(\mathcal{F}, P) : J \subset I, |J| = N - n\} \quad (19)$$

at least approximately. Problem (19) is known as *n-median problem* and as *NP-hard*.

Unfortunately, for many function classes $\mathcal{F}$, it is impossible to determine $D_J(\mathcal{F}, P)$ as well as the optimal redistribution explicitly. In particular, this is true for models with probabilistic constraints and for two-stage mixed-integer stochastic programs in which case (rectangular, polyhedral) discrepancies appear as distances $d_{\mathcal{F}}$ [21,22]. For discrepancies, however, the inner problem may be solved by linear programming [21]. For two-stage linear stochastic programs, the

integrands $f_0(x, \cdot)$ in Equation (2) are often proportional to certain elements of

$$\mathcal{F}_r(\Xi) = \{f : \Xi \rightarrow \mathbb{R} : |f(\xi) - f(\tilde{\xi})| \leq c_r(\xi, \tilde{\xi}), \\ \forall \xi, \tilde{\xi} \in \Xi\},$$

for some $r \in \mathbb{N}$ and with the (cost) function c_r defined by

$$c_r(\xi, \tilde{\xi}) := \max\{1, \|\xi\|^{r-1}, \|\tilde{\xi}\|^{r-1}\} \|\xi - \tilde{\xi}\| \\ (\xi, \tilde{\xi} \in \Xi)$$

(see Refs 1 and 23). The corresponding distance $\zeta_r := d_{\mathcal{F}_r}$ is known as *Fortet–Mourier metric* of order r . In the latter case the inner problem is explicitly solvable, and it holds

$$D_J(\mathcal{F}_r, P) = \sum_{j \in J} p_j \min_{i \notin J} \hat{c}_r(\xi^i, \xi^j) \quad (20)$$

$$\bar{q}_i = p_i + \sum_{\substack{j \in J \\ i(j)=i}} p_j \text{ and}$$

$$i(j) \in \arg \min_{i \notin J} \hat{c}_r(\xi^i, \xi^j), i \in I \setminus J, \quad (21)$$

that is, the redistribution rule consists in adding the probability of a deleted scenario indexed by $j \in J$ to the probability of a remaining scenario that is nearest to ξ^j with respect to the distance $\hat{c}_r$ on $\text{supp}(P)$. The so-called reduced cost $\hat{c}_r$ has the representation

Forward algorithm for scenario reduction

Step 0: $J^{[0]} := \{1, \dots, N\}$.

Step k: $u_k \in \arg \min_{u \in J^{[k-1]}} \sum_{j \in J^{[k-1]} \setminus \{u\}} p_j \min_{i \notin J^{[k-1]} \setminus \{u\}} \hat{c}_r(\xi^i, \xi^j),$
 $J^{[k]} := J^{[k-1]} \setminus \{u_k\}.$

Step n+1: Redistribution with $J := J^{[n]}$ via (21).

Similarly, the idea of the backward algorithm is based on the second special case of problem (19) with expression (20) for $n = N - 1$.

SCENARIO TREES FOR MULTISTAGE STOCHASTIC PROGRAMS

The special feature of multistage stochastic programs (see *Two-Stage Stochastic*

$$\hat{c}_r(\xi^i, \xi^j) := \min \left\{ \sum_{k=1}^{\ell-1} c_r(\xi^{i_k}, \xi^{i_{k+1}}) : \ell \in \mathbb{N}, \right. \\ \left. i_k \in I, k = 1, \dots, \ell, i_1 = i, i_\ell = j \right\}.$$

Two simple heuristic algorithms for solving Equation (19) are proposed in Refs 19 and 20: the *forward (selection)* and the *backward (reduction) heuristic*. To give an idea of the heuristics, we give a short description of the forward algorithm. Its basic idea originates from the simple structure of Equation (19) with Equation (20) for the special case $n = 1$. It is of the form

$$\min_{u \in \{1, \dots, N\}} \sum_{\substack{j=1 \\ j \neq u}}^N p_j \hat{c}_r(\xi^u, \xi^j).$$

If the minimum is attained at u^* , the index set $J = \{1, \dots, N\} \setminus \{u^*\}$ solves Equation (19) for $n = 1$. The scenario ξ^{u^*} is taken as the first element of $\text{supp}(Q)$. Then the separable structure of D_J is exploited to determine the second element of $\text{supp}(Q)$ while the first element is fixed (see Fig. 1). The process is continued until n elements of $\text{supp}(Q)$ are selected.

Programs: Introduction and Basic Properties consists in imposing information constraints on the decisions. The information flow is modeled by a filtration of σ -fields $\mathcal{A}_t$, $t = 1, \dots, T$, which is associated to the stochastic input process $\xi = (\xi_t)_{t=1}^T$ defined on a probability space $(\Omega, \mathcal{A}, \mathbb{P})$. Typically, it is required that the σ -field $\mathcal{A}_t$ is generated by the random vector $(\xi_1, \dots, \xi_t)$. Then the information or *nonanticipativity* constraint

Figure 1. Illustration of selecting the first, second, and third scenario out of $N = 5$.

means measurability of the decisions x_t with respect to $\mathcal{A}_t$ for every $t = 1, \dots, T$. Mostly, $t = 1$ refers to the present. Thus, ξ_1 is deterministic and $\mathcal{A}_1 = \{\emptyset, \Omega\}$.

Clearly, any scenario-based approximation of the underlying probability distribution P of ξ has to reflect the growth of the σ -fields. Hence, the scenarios need to be *tree-structured*. In general, there are two ways to generate scenario trees, namely, (i) a tree-structure is prescribed and scenarios are generated via conditional distributions for increasing t starting with a root at $t = 1$, or (ii) in a first step, a number of scenarios is generated for the whole horizon $t = 1, \dots, T$ based on the distribution P and according to some method reported in the section titled “Scenario Generation Techniques.” Secondly, a tree structure is generated successively by bundling scenarios.

Several specific techniques for generating scenario trees are known from the literature. We refer to the survey [24] and the more recent articles [15–17, 25–34]. Most of them are discussed in the introduction of Ref. 26.

Finally, we review an application of scenario reduction techniques (see the section titled “Scenario Reduction”) to generate scenario tree. We consider an original (nonstructured) scenario set $\{\xi^1, \dots, \xi^N\}$, satisfying the root condition $\xi_1^i = \xi_1^*$, $i = 1, \dots, N$, and the parameter sets $\{1, \dots, t\}$ for increasing t and start at $t = 2$ with the reduction of the original scenario set restricted to $t = 2$. This leads to (say) k_2 remaining scenarios and certain clusters C_2^k of scenarios for $k = 2, \dots, k_2$ that are associated to one of the remaining scenarios via the next neighbor property. In general, we obtain (disjoint) partitions or clusters

$$C_t := \{C_t^1, \dots, C_t^{k_t}\}, \quad (k_t \in \mathbb{N})$$

of the index set $I = \{1, \dots, N\}$ for every $t = 2, \dots, T$. The following *forward algorithm* leads to a scenario tree process ξ_{tr} whose structure may be controlled by certain tolerances ε_t , $t = 2, \dots, T$.

Algorithm: *Forward scenario tree generation*

Step 1: Initialization

Set $C_1 = \{I\}$, $k_1 = 1$ and $t := 2$.

Step 2: Cluster computation Let $C_{t-1} = \{C_{t-1}^1, \dots, C_{t-1}^{k_{t-1}}\}$. Perform scenario reduction w.r.t. the Fortet–Mourier metric ζ_r for every scenario subset $\{\xi_t^i\}_{i \in C_{t-1}^k}$ separately for every $k \in \{1, \dots, k_{t-1}\}$ and only with respect to the t th component. Define index sets J_t^k and I_t^k of deleted and remaining scenarios and mappings $i_t^k : J_t^k \rightarrow I_t^k$ such that

$$i_t^k(j) \in \arg \min_{i \in I_t^k} \hat{c}_r(\xi_t^i, \xi_t^j), \quad (j \in J_t^k),$$

according to the rule (21). Define the partition C_t and the mapping $\alpha_t : I \rightarrow I$ by

$$C_t := \left\{ \alpha_t^{-1}(i) \mid i \in I_t^k, k = 1, \dots, k_{t-1} \right\} \quad \text{and} \quad \alpha_t(j) = \begin{cases} i_t^k(j), & j \in J_t^k, \\ j, & \text{else.} \end{cases} \quad (22)$$

C_t is a refinement of the partition C_{t-1} . If $t < T$ perform the cluster computation for $t = t + 1$ and go to Step 2.

Step 3: Tree generation According to the partition C_T and the mapping α_T (see Eq. 22) the scenario tree process ξ_{tr} is defined such that its k th scenario is

$$\xi_{\text{tr}}^k = \left(\xi_1^*, \xi_2^{\alpha_2(i)}, \dots, \xi_t^{\alpha_t(i)}, \dots, \xi_T^{\alpha_T(i)} \right) \quad \text{for some } i \in C_T^k$$

with probability $q_k := \sum_{i \in C_T^k} p_i$ for every $k = 1, \dots, k_T$. The error at step t is given by

$$\text{err}_t := \sum_{k=1}^{k_t-1} \sum_{j \in J_t^k} p_j \min_{i \in I_t^k} \hat{c}_r(\xi_t^i, \xi_t^j).$$

Hence, the generation procedure may be controlled by the condition $\text{err}_t \leq \varepsilon_t$ for every $t = 2, \dots, T$. We refer to Ref. 26 for further information and some computational experience.

SCHEDULING SEASIDE RESOURCES AT CONTAINER PORTS

FRANK MEISEL
Institute of Business Studies,
Martin-Luther-University
Halle-Wittenberg, Halle, Germany

INTRODUCTION

Container terminals (CTs) in seaports are logistics facilities that handle containerized cargo by serving vessels, trucks, and trains. They link the different modes of transportation for providing access of a terminal's hinterland to international trade routes. The general layout and the available equipment alternatives of seaport terminals are sketched in Fig. 1. At the seaside, vessels moor at the berths of a terminal where quay cranes (QCs) transship the containers between the vessels and the terminal area. The transport of containers between the terminal areas is usually performed by yard trucks or by straddle carriers. If yard trucks are used for the transport operations, cranes are deployed within the yard for stacking and retrieving containers. Automated variants of yard trucks and straddle carriers are called automated guided vehicles (AGVs) and automated lifting vehicles (ALVs), respectively. These vehicles are guided completely by a terminal's control system and need no driver onboard. For details on the technical equipment, the interested reader is referred to the studies of various authors [1–5] and to the websites of equipment manufacturers [6–11].

From the point of view of vessel operators, the service time of a vessel at a terminal is unproductive and should be kept as short as possible. They therefore expect that terminals provide sufficient handling capacity in terms of quay space, technical equipment, and workforce. This led to substantial extensions of existing terminals, new building of terminals, and upgrading of handling equipment throughout terminals worldwide in recent years. For details on

such projects; see Ilmer [13]. Strategic and tactical decisions that come along with these projects are, for example, to determine locations and layouts of new terminals and to decide on the equipment to use.

Next to the provision of service capacity, the operational performance of available terminal resources is a further driver of service quality. Fast and reliable services require minimizing delays before the service of a vessel starts and avoiding large handling times due to the low productivity of the equipment [14,15]. Hence, the best possible utilization of the available resources through effective planning and scheduling of equipment and workforce enables fast service operations and creates competitive advantage for a terminal. Therefore, various CT planning problems have been identified and research increasingly supports practitioners by developing models and algorithms for solving these management tasks. Table 1 lists the most often addressed planning tasks. This article puts focus on the operational planning and scheduling problems related to the berth space and quay crane resources of a terminal, namely the berth allocation problem, the quay crane assignment problem, and the quay crane scheduling problem.

The article is organized as follows. For supporting readers with a comprehensive introduction to seaport operations planning, the section titled “An Overview of Operational Planning and Scheduling Problems” briefly summarizes those planning problems of Table 1 that are not the focus of this article. A more detailed version of these explanations is given by Meisel [12]. Further overviews on CT operations planning are provided by various authors [16–22]. The sections titled “Berth Allocation and Quay Crane Assignment” and “Quay Crane Scheduling” provide in-depth studies on the planning problems related to the seaside resources. The section titled “Berth Allocation and Quay Crane Assignment” explains the problems of berth allocation and quay crane assignment in detail, provides a comprehensive literature survey based on Bierwirth and Meisel [23], and presents two models proposed in recent studies. The section titled “Quay

Figure 1. Schematic cross-sectional view of a container terminal [12].

Table 1. Major Operational Planning Tasks of a Container Terminal

Planning Task	Decisions to Make
Berth allocation	Berthing positions and berthing times of vessels to be served
Quay crane assignment	Number of QCs that serve a vessel Specific cranes to use for the service
Quay crane scheduling	Scheduling of loading and unloading operations for a vessel
Stowage planning	Slot positions of export containers within a vessel
Yard management	Reservation of yard capacity for liner services Selection of storage locations for individual containers Remarshalling operations of containers
Yard crane scheduling	Deployment of cranes to yard blocks Scheduling of stackings and retrievals of containers
Horizontal transport management	Assignment of vehicles to QCs Scheduling of transport orders on vehicles
Hinterland operations planning	Service order of trucks and trains Sequencing loading and unloading operations
Workforce planning	Provision of workforce capacity Scheduling of labor tasks

Crane Scheduling” presents the quay crane scheduling problem at the same level of detail. The final section concludes this article.

AN OVERVIEW OF OPERATIONAL PLANNING AND SCHEDULING PROBLEMS

Stowage planning means to arrange containers onboard a vessel by assigning a slot position to every container that has to be

transported from a considered terminal to successive terminals on a vessel’s route [24]. Stowage planning is often made on two levels of aggregation, where a coarse stowage plan is generated by assigning container classes to slots, and, then, a precise stowage plan is generated by assigning individual containers to slots of their container class [25]. The assignment of containers to slots has to respect container attributes like size and

weight as well as stability constraints of a vessel [26,27]. A typical objective is the minimization of reshuffling of containers, which occurs whenever a container dedicated to a late terminal in the vessel's route is stowed on top of a container that has to be unloaded earlier [24,28].

Yard management comprises reserving yard blocks for liner services, selecting storage locations for individual containers, and planning remarshalling operations. Yard blocks have to be reserved for buffering import and export containers of a calling vessel. For maximizing the utilization of yard space over time, space is reserved dynamically for a calling vessel [29]. When selecting storage locations of individual containers, minimization of transfer time of vehicles or minimization of reshuffles is often the pursued objective [30]. Dekker *et al.* [31] show that a stacking policy in which export containers of a same class are stored in the same yard stack reduces reshuffling at the time of the vessel service. Yard remarshalling means to reposition containers if they are not stored within their dedicated area, or if their stacking order requires reshuffling. These operations are executed ahead of the service process of a vessel in periods of low workload. The objective is to minimize the number of moves performed to restack and reposition containers [32,33].

Yard crane scheduling comprises the deployment of cranes at yard blocks and the scheduling of container stacking and retrieval operations. Deployment of yard cranes (YCs) means to dynamically assign cranes to those yard blocks where stacking and retrieval operations have to be performed. The pursued objective is the minimization of an unfinished workload, which needs to be carried from one period to the subsequent planning period [3,34]. The order of stacking and retrieving containers in the yard is usually preset by the schedules of the QCs. Scheduling YC operations is still required, for example, to retrieve the containers of a yard bay at a minimum number of reshuffle operations [35,36]. If two YCs operate within 1 yard block, crane interference needs to be considered [37,38]. Since YC operations are interrelated with further terminal

operations, scheduling of these cranes is often investigated in combination with stowage planning or QC scheduling [39–41].

Horizontal transport management comprises the assignment of vehicles to cranes and the scheduling of transport orders on the vehicles. With the first decision, vehicles are either assigned exclusively to QCs or they are pooled where each vehicle serves different QCs [42–44]. The pooling strategy requires fewer vehicles and reduces empty movement but entails more complicated dispatching. Scheduling transport orders on terminal vehicles is made on a short planning horizon of a few minutes to respect the actual progress of QC operations. Since most vehicle types carry only a single container at a time, pickup-and-delivery routing problems have to be solved here. One exception is dual-load AGVs, which can transport two 20' containers at a time [45,46]. If automated vehicles are used, routing and traffic control must be managed thoroughly to avoid blockages of concurrent loading and unloading processes (so-called *deadlocks*) [47–49].

Hinterland operations concern the service of trains and external trucks. Planning these service operations is often similar to planning the service of vessels with the exception of modified technical and organizational constraints and objectives. For example, since containers are not stacked on trains, terminal operators are more flexible in sequencing the loading and unloading operations. Consequently, a reduction potential exists for empty travel of terminal vehicles and for reshuffling of containers in the yard. Further objectives are the minimization of shunting activities of trains within the terminal [18], the minimization of waiting time of external trucks [50], and the minimization of the number of cranes used for serving external trucks and trains [51].

Workforce planning comprises the provision of sufficient workforce capacity and the scheduling of labor tasks. To decide on an appropriate workforce capacity, workforce requirements must be estimated, for example, by considering the projected workload of the horizontal transport system within the coming work shifts [42,43]. At the seaside of a terminal, the required

workforce capacity is defined by the QCs that must be manned within a shift. Therefore, Bierwirth and Meisel [52] minimize the number of manned QCs per work shift within a combined berth allocation and QC assignment problem. For a given workforce, Kim *et al.* [53] investigate the assignment of individual operators to QCs, YCs, and yard trucks with respect to work plans and the laborer's skills. Scheduling of labor tasks is often covered by the already described equipment scheduling problems but it is sometimes treated as an individual planning problem, for example, if operators are required to connect reefer containers to electric supply [54]. Objectives of labor task scheduling include the minimization of tardy task completions [54] and the minimization of the number of required laborers [55].

BERTH ALLOCATION AND QUAY CRANE ASSIGNMENT

Problem Description

Container vessels call at a terminal according to fixed liner schedules. From these schedules, the set of vessels to be served within a planning horizon is known to the terminal management, together with relevant information like expected times of arrival and an approximate number of the containers to load and unload. In the *berth allocation problem* (BAP), a berthing position and a berthing time are assigned to each vessel that is to be served within the planning horizon. A typical planning horizon is a few days up to one week. The decisions made have to respect the layout of a CT, which means that vessels must be moored within the boundaries of the quay and alongside the straight segments of the quay wall; see Fig. 2. Differing from naval ports and general cargo terminals where vessels may be repositioned

to other berthing positions [56–58], container vessels stay at the assigned position during the entire service to keep the handling time as short as possible. The projected berthing time, handling time, and berthing position of a vessel determine the temporal occupation of the allocated berth space, that is, the time span within which no other vessel can be moored at this position. Figure 3 provides an illustration of a berth plan for 29 vessels at a terminal with a quay length of 1000 m and a planning horizon of 114 h. The plan shows the projected berthing position and berthing time for each vessel. The most frequently pursued objective in berth allocation models is the minimization of vessel waiting time in order to achieve earliest possible departure times [59–61].

Handling times of vessels are important input for the BAP. Since vessel handling times depend strongly on the number of serving cranes, the problem of assigning quay cranes to vessels is closely interrelated with berth allocation and both problems are often solved jointly [62]. The plan shown in Fig. 3, therefore, also comprises an assignment of cranes to vessels. It illustrates the number of cranes assigned to each vessel on an hourly basis and the utilization of the 10 cranes available at this terminal for each period of the planning horizon. The task of the *quay crane assignment problem* (QCAP) is to allocate sufficient QC capacity to every vessel for fulfilling the required loading and unloading operations of containers. The major decision to make is the number of cranes to assign to each of the vessels that are served simultaneously, which is sometimes also referred to as the *crane split* [18]. This decision clearly impacts the handling time of a vessel, because a larger number of cranes at a vessel can fulfill the loading and unloading operations more quickly. However, owing to mutual crane interference, additional cranes may lower

Figure 2. Berthing vessels with respect to the terminal layout.

Figure 3. An example of a berth plan and crane assignment.

the average crane productivity, such that a decreasing marginal productivity is often observed at CTs. Therefore, the maximum number of cranes to assign to a vessel is usually bounded, for example, to two to six cranes per vessel depending on its size [63]. Obviously, the total number of QCs available at the terminal must be considered when distributing cranes among vessels. Moreover, a feasible assignment of cranes to vessels has to respect the berthing times preset by the berth plan. If crane interference is considered within crane assignment, one objective is to minimize the total handling time of vessels by keeping crane productivity loss as low as possible. A further objective can be to find an assignment that allows serving vessels without exceeding the departure times projected in the berth plan [64]. The second decision of the QCAP is to decide on the specific QCs to assign to a vessel. Here, one must take into account that QCs are mounted on a rail track alongside the quay and, thus, they cannot pass each other. Therefore, a specific assignment is only feasible if the relative positions of cranes are preserved at all times. When deciding on the specific QCs to serve a vessel, the number of crane setups at vessels

[62] or the movement of cranes between vessels [65] can be minimized.

A Review of Models Proposed in the Literature

Models for berth allocation are distinguished depending on the layout of the berths into discrete problems, continuous problems, and hybrid problems [23,66]. In discrete problems, the quay is partitioned into a number of sections, called *berths*. Only one vessel can be served at a berth at a time. In a continuous problem, there is no partitioning of the quay, that is, vessels can berth at arbitrary positions within the boundaries of the quay. In hybrid layouts, the quay is partitioned into berths, but large vessels may occupy more than one berth while small vessels may share a berth. Moreover, in the so-called *static problems*, vessels would have already arrived at the terminal when berth planning is to be done, whereas in dynamic problems the arrival times of vessels within the planning horizon must be respected [67].

The discrete BAP has been studied in the static variant by Imai *et al.* [67,68], Hansen and Oğuz [69], and Lee *et al.* [70]. The objective pursued in the four papers is to minimize the vessels' port stay time, which is the total of waiting and handling time of a vessel at

the terminal. Dynamic variants of the discrete BAP have been investigated in a larger number of studies but with different objectives. The minimization of port stay times of vessels within a discrete dynamic BAP has been investigated by various authors [59–61,67,69,71–76]. The minimization of tardy departures of vessels is investigated in Refs 59, 77 and 78. Imai *et al.* [79] minimize the weighted number of vessels that cannot be served until a given due date. In the work of Giallombardo *et al.* [80,81] and Hansen *et al.* [82] also, the service costs of vessels depend on their assigned berth and, hence, berthing positions are taken up in the objective function. Most of the above studies assume that the handling time of a vessel depends on its assigned berth. The studies of Lee *et al.* [70], Imai *et al.* [75], Liang *et al.* [78], and Giallombardo *et al.* [80,81] additionally incorporate assignment or scheduling decisions for the QCs into berth allocation models to determine more realistic handling times for the vessels.

The continuous static BAP has been investigated by various authors [62,83–86]. Guan *et al.* [84] propose to minimize the total weighted completion time of vessels, whereas Lee *et al.* [83] and Oğuz *et al.* [86] propose to minimize the maximum completion time among the vessels. In the models of Park and Kim [62] and Rashidi [85] a combination of port stay times, tardiness penalties, and berthing position related cost is minimized. As observed for the discrete BAP, also the continuous BAP attracted much more research in its dynamic variant [52,64–66,87–104]. The studies of various authors [64–66,87,88,97,101,103,104] pursue the minimization of waiting and/or handling time of vessels. Tardiness objectives are addressed by various authors [65,89–92,98,100,104]. In the continuous BAP also the berthing positions of vessels are considered in the objective function, for example, to minimize the deviation from a desired berthing position for a vessel or to minimize the total berth space occupied by the vessels [62,85,88–96,104]. In several studies on the continuous BAP, it is assumed that vessel handling times are given, fixed, and independent of the decisions made within

berth allocation. This assumption is relaxed in Imai *et al.* [66] and Meisel and Bierwirth [98], where vessel handling times depend on the berthing position of a vessel, and in Refs 52, 62, 64, 65, 85, 86 and 98–104 where QC assignment or QC scheduling decisions are incorporated into berth allocation models.

BAP models for hybrid layouts, where large vessels can occupy several berths or small vessels can share the same berth are presented in Refs 61, 105–112. All papers investigate the dynamic variant of a hybrid BAP. The pursued objectives are the minimization of vessel waiting and/or handling time [61,105,106,108–110,112] and the minimization of a measure related to the berthing position of vessels [107,111]. The handling times of vessels are assumed to be given and fixed [105–107], or assumed to depend on the berthing position of vessels [61,108–111], or they are determined by an additional assignment of cranes to vessels [112].

Two Examples of Models Proposed in the Literature

The following subsections present two examples of berth allocation models that are proposed in the recent literature. The models of Imai *et al.* [79] and Meisel and Bierwirth [98] have been selected to illustrate the broad range of different issues that are covered by the published studies. The study of Imai *et al.* [79] is of interest, because in their model, a certain service level is guaranteed for the vessels through a restricted maximum waiting time. The assignment of quay cranes to vessels is not in the scope of this model. In Meisel and Bierwirth [98] continuous berth allocation and crane assignment are solved jointly to respect the impact of berth space availability and crane utilization on the service quality of vessels.

A Model for Discrete Berth Allocation with a Waiting Time Limit for Vessels. Discrete dynamic berth allocation with a waiting time limit for vessels has been introduced by Imai *et al.* [79]. In this problem, a terminal is considered where the quay is partitioned into Q berths. Berths $1, 2, \dots, Q-1$ are owned by the terminal operator who decides on the berth allocation. Berth Q serves as a

subcontracted external buffer, which handles vessels in situations of excessive workload at terminals 1 to $Q - 1$. $B = \{1, 2, \dots, Q\}$ is the set of all berths. For each berth $i \in B$, S_i is the point in time when the berth becomes available, for example, after finishing the service of previously assigned vessels.

A set of vessels $V = \{1, 2, \dots, n\}$ is projected to be served at the terminal, where n is the total number of vessels. For each vessel $j \in V$, an arrival time A_j is given and also a handling time C_{ij} that is needed for serving vessel j at berth $i \in B$. Moreover, a waiting time limit L_j is given for vessel j to ensure a certain level of service quality. Vessels that cannot be served at one of the berths 1 to $Q - 1$ without exceeding the waiting time limit are assigned to the external berth Q . It is assumed that the external berth shows sufficient capacity for handling vessels quickly within acceptable waiting times. Further assumptions are as follows:

- Each berth can handle one vessel at a time.
- Each berth shows sufficient water depth to berth arbitrary vessels.
- The handling time of a vessel depends solely on its allocated berth.
- Vessels are served without preemption, that is, once the process has been started to serve a vessel it is not interrupted until the service is completed.

The decisions to make are to assign a berth to each calling vessel and to find a sequence for serving the vessels at the berths. Both decisions are represented by the binary variable x_{ijk} , which is set to 1, if vessel j is served as the $(n - k + 1)$ th last vessel at berth i . Further decision variables y_{ijk} measure the idle time of berth i between the departure of the $(n - k + 2)$ th last vessel and the arrival of the $(n - k + 1)$ th last vessel when j is served as the $(n - k + 1)$ th last vessel. The objective of the berth allocation process is the minimization of the total handling time of vessels at the external berth Q , which corresponds to a minimum payment of service charges to the external berth operator for handling vessels.

The discrete BAP with a waiting time limit is formulated as follows:

minimize

$$Z = \sum_{j \in V} \sum_{k \in U} C_{Qj} \cdot x_{Qjk} \quad (1)$$

s.t.

$$\sum_{i \in B} \sum_{k \in U} x_{ijk} = 1 \quad \forall j \in V, \quad (2)$$

$$\sum_{j \in V} x_{ijk} \leq 1 \quad \forall i \in B, k \in U, \quad (3)$$

$$S_i - A_j + \sum_{l \in V} \sum_{m \in P_k} (C_{il}x_{ilm} + y_{ilm}) + y_{ijk} + (x_{ijk} - 1) \cdot M \leq L_j \quad \forall i \in B \setminus \{Q\}, \\ j \in V, k \in U, \quad (4)$$

$$\sum_{l \in V} \sum_{m \in P_k} (C_{il}x_{ilm} + y_{ilm}) + y_{ijk} - (A_j - S_i)x_{ijk} \geq 0 \quad \forall i \in B, j \in W_i, k \in U, \quad (5)$$

$$x_{ijk} \in \{0, 1\} \quad \forall i \in B, j \in V, k \in U, \quad (6)$$

$$y_{ijk} \geq 0 \quad \forall i \in B, j \in V, k \in U. \quad (7)$$

Objective (1) minimizes the total handling time of vessels that are allocated to the external terminal. Here, $U = \{1, 2, \dots, n\}$ denotes a set of service orders that is used for indexing the vessels within the service sequence at a berth. Constraint set (2) ensures that every vessel gets assigned a berth and a position within the service order of that berth. Constraints (3) enforce that every berth serves up to one ship at any time. Constraints (4) assure that vessels do not wait longer than the time limit if they are served at one of the berths 1 to $Q - 1$. For this inequality, P_k is a subset of U such that $P_k = \{p \mid p < k \in U\}$, that is, $P_k = \{1, 2, \dots, k - 1\}$, and M is a sufficiently large value. In these constraints, the waiting time of a vessel is evaluated as a function of the ready time of the assigned berth, the arrival time of the vessel, the handling time of preceding vessel services, and berth idle times caused by late arriving vessels in the service sequence. Constraints (5) enforce that the service of a vessel cannot start before the arrival time. In this constraint, W_i is the subset of those vessels $j \in V$ that arrive after the

ready time of berth i , that is, $A_j \geq S_i$. The constraints (6) and (7) define domains for the decision variables.

A Model for Continuous Berth Allocation and Quay Crane Assignment. The joint problem of continuous berth allocation and crane assignment is formally described as follows. A terminal with a quay of length L is considered, where Q QCs are available for serving vessels. The planning horizon of the problem is H hours, where T is a corresponding set of 1 h time periods, that is, $T = \{0, 1, \dots, H - 1\}$.

A set of vessels $V = \{1, 2, \dots, n\}$ is projected to be served within the planning horizon, where n is the total number of vessels. The crane capacity demand of vessel $i \in V$ to fulfill all loading and unloading operations is m_i QC-hours. The minimum and maximum numbers of QCs to assign to the vessel are denoted by $r_i^{\min}$ and $r_i^{\max}$, yielding the range $R_i = [r_i^{\min}, r_i^{\max}]$. The length of vessel i is denoted by l_i and a desired berthing position b_i^0 is specified for every vessel within the vicinity of those yard areas that have been reserved for storing its import and export containers. Furthermore, an expected time of arrival ETA_i is given. Berthing the vessel earlier than ETA_i is possible by a speedup on its journey to the terminal. The realizable speedup, however, is bounded to an earliest starting time $EST_i \leq ETA_i$, that is, the vessel cannot be berthed earlier than EST_i . Finally, an expected finishing time EFT_i and a latest finishing time LFT_i are given for the vessel.

The following assumptions are made:

- Each quay position shows sufficient water depth to berth arbitrary vessels.
- Vessels are served without preemption.
- It takes no time to move a QC from one vessel to another vessel.
- Every crane has the technical capability to serve every vessel. Furthermore, the cranes are identical, that is, they show the same maximum productivity.

The decisions to make are to determine a berthing time s_i , a berthing position b_i , and the number of QCs to assign to each vessel $i \in V$ in its service periods such that a cost

measure is minimized. The berthing time s_i of a vessel corresponds to the start of the first period with cranes assigned, whereas its departure time e_i is defined by the end of the last period with cranes assigned. The time span between s_i and e_i defines the handling time of vessel i . The assignment of cranes to vessels is represented by a binary decision variable r_{itq} . It is set to 1 if and only if exactly q QCs are assigned to vessel i at time t . To evaluate a solution, the deviation from the desired berthing position $\Delta b_i = |b_i^0 - b_i|$, the necessary speedup $\Delta ETA_i = (ETA_i - s_i)^+$, and the tardiness $\Delta EFT_i = (e_i - EFT_i)^+$ are determined for each vessel i . Figure 4 illustrates the vessel data and variables. The following binary decision variables are additionally introduced for the mathematical formulation of the outlined problem: r_{it} is set to 1 if at least one QC is assigned to vessel i at time t . u_i is set to 1 if the finishing time of vessel i exceeds LFT_i . y_{ij} is set to 1 if vessel i is berthed below vessel j , that is, $b_i + l_i \leq b_j$. Finally, z_{ij} is set to 1 if the service of vessel i ends not later than when the service of vessel j starts.

The continuous BAP with integrated QC assignment is formulated as follows:

minimize

$$Z = \sum_{i \in V} \left(c_i^1 \cdot \Delta ETA_i + c_i^2 \cdot \Delta EFT_i + c_i^3 \cdot u_i + c^4 \cdot \sum_{t \in T} \sum_{q \in R_i} (q \cdot r_{itq}) \right) \quad (8)$$

s.t.

$$\sum_{t \in T} \sum_{q \in R_i} (q^\alpha \cdot r_{itq}) \geq (1 + \beta \cdot \Delta b_i) \cdot m_i \quad \forall i \in V, \quad (9)$$

$$\sum_{i \in V} \sum_{q \in R_i} (q \cdot r_{itq}) \leq Q \quad \forall t \in T, \quad (10)$$

$$\sum_{q \in R_i} r_{itq} = r_{it} \quad \forall i \in V, \quad \forall t \in T, \quad (11)$$

$$\sum_{t \in T} r_{it} = e_i - s_i \quad \forall i \in V, \quad (12)$$

Figure 4. Vessel data—waiting before berthing (a) and speedup case (b).

$$(t+1) \cdot r_{it} \leq e_i \quad \forall i \in V, \forall t \in T, \quad (13)$$

$$t \cdot r_{it} + H \cdot (1 - r_{it}) \geq s_i$$

$$\forall i \in V, \forall t \in T, \quad (14)$$

$$\Delta b_i \geq b_i - b_i^0 \quad \forall i \in V, \quad (15)$$

$$\Delta b_i \geq b_i^0 - b_i \quad \forall i \in V, \quad (16)$$

$$\Delta ETA_i \geq ETA_i - s_i \quad \forall i \in V, \quad (17)$$

$$\Delta EFT_i \geq e_i - EFT_i \quad \forall i \in V, \quad (18)$$

$$M \cdot u_i \geq e_i - LFT_i \quad \forall i \in V, \quad (19)$$

$$b_j + M \cdot (1 - y_{ij}) \geq b_i + l_i$$

$$\forall i, j \in V, i \neq j, \quad (20)$$

$$s_j + M \cdot (1 - z_{ij}) \geq e_i \quad \forall i, j \in V, i \neq j, \quad (21)$$

$$y_{ij} + y_{ji} + z_{ij} + z_{ji} \geq 1 \quad \forall i, j \in V, i \neq j, \quad (22)$$

$$s_i, e_i \in \{EST_i, \dots, H\} \quad \forall i \in V, \quad (23)$$

$$b_i \in \{0, 1, \dots, L - l_i\} \quad \forall i \in V, \quad (24)$$

$$\Delta ETA_i, \Delta EFT_i \geq 0 \quad \forall i \in V, \quad (25)$$

$$r_{itq}, r_{it}, u_i, y_{ij}, z_{ij} \in \{0, 1\}$$

$$\forall i, j \in V, \forall t \in T, \forall q \in R_i. \quad (26)$$

The optimization model pursues the minimization of the total cost arising from the service of all vessels within the planning horizon. For every vessel, speedup cost for berthing earlier than ETA_i , tardiness cost for exceeding the expected finishing time EFT_i , and penalty cost for exceeding the latest allowed finishing time LFT_i are summed up in Equation (8). The corresponding cost rates are denoted as c_i^1 , c_i^2 , and c_i^3 . While speedup cost and tardiness cost grow constantly in time, penalty cost is incurred only once, if the departure of the vessel is beyond the latest allowed finishing time LFT_i . A fourth cost type is added to evaluate the utilized QC-hours within a berth plan. The cost rate per QC-hour is denoted as c^4 . This objective accounts for the decreasing marginal productivity of QCs and the resulting trade-off between accelerating the handling of a vessel and the operational cost of QCs.

Constraints (9) ensure that every vessel receives the required QC capacity with respect to productivity losses by QC interference and the chosen berthing position. Interference among QCs leads to reduced marginal productivity. Several authors proposed to model this productivity loss using a so-called *interference exponent* [86,113–115]. For a given interference exponent α ($0 < \alpha \leq 1$), the productivity obtained from assigning q cranes to a vessel for 1 h is given by a total of q^α QC-hours. This effect is incorporated on the left-hand side of constraint (9). The productivity of a terminal is also affected by the workload of horizontal transport means. This workload is minimal if a vessel berths at its desired berthing position b_i^0 .

If the actually chosen berthing position is apart from the desired position, the load of the horizontal transport increases, which can also lead to a productivity loss of cranes due to starvation. This productivity loss is modeled here by an increase in the vessel's QC capacity demand. Let $\beta \geq 0$ denote the relative increase of QC capacity demand per unit of berthing position deviation. Hence, a vessel positioned Δb_i quay segments away from its desired berthing position requires $(1 + \beta \cdot \Delta b_i) \cdot m_i$ QC-hours to be served as is modeled on the right side of constraint (9).

Constraints (10) enforce that at most Q cranes are utilized in a period. In every period a certain number of QCs is assigned to every vessel, which is either zero or taken from the range R_i . A consistent setting of the corresponding variables r_{it} and r_{itq} is ensured by Equation (11). Constraints (12–14) set the starting times and ending times for serving vessels without preemption. Constraints (15–18) determine the deviations from the desired berthing position, expected arrival time, and expected finishing time for each vessel. Variable u_i indicates whether the handling of vessel i ends later than LFT_i . It is set by constraints (19) where M denotes a large positive number. Constraints (20) and (21) set the variables y_{ij} and z_{ij} , which are used to avoid overlapping the handling of vessels in the space-time diagram in constraints (22). The arrival of a vessel can be expedited to at most the earliest starting time EST_i . Moreover, the planning horizon H defines a limit on the departure time of the vessels. Both aspects are reflected in constraints (23). Constraints (24) ensure that each vessel is positioned within the quay boundaries. Constraints (25) and (26) define domains for the remaining decision variables.

Discussion of the Models. The models presented cover different issues of berth allocation. When facing a practical terminal situation, one model will likely fit better than the other. For example, if the quay must be partitioned into distinct berths due to the layout of the terminal, then a discrete BAP model is needed such as that discussed in the section titled “A Model for Discrete Berth Allocation with a Waiting Time Limit for

Vessels.” Moreover, when each berth holds a set of dedicated cranes, the assumption that vessel handling times depend solely on the allocated berth is also justified. In this case, all cranes at a berth will jointly serve an allocated vessel and, therefore, the resulting vessel handling time at a berth can be estimated precisely. An explicit assignment of cranes to vessels is not required. In contrast, when the quay of a terminal is linear, terminal operators will exploit the flexibility in choosing berthing positions and assigning cranes for improved resource utilization and better service quality. Using a model for continuous berth allocation with integrated crane assignment such as that in the section titled “A Model for Continuous Berth Allocation and Quay Crane Assignment” is essential for such a terminal. Here, handling times are adjustable from assigning cranes to vessels. The resulting variable occupation of the quay space impacts on the berth allocation decisions. The flexibility gained in service operations is accounted for by a more complex measurement of service quality in the objective function. Moreover, operational cost for utilizing the crane resource should also be considered in such a situation as is done in the model presented.

Both continuous and discrete dynamic BAP models are in general $\mathcal{NP}$ -hard optimization problems. Therefore, heuristics are proposed in the literature for solving problem instances of practical size. For the models investigated here, a genetic algorithm, a squeaky wheel optimization, and a tabu search are proposed by Imai *et al.* [79] and Meisel and Bierwirth [98].

QUAY CRANE SCHEDULING

Problem Description

In the quay crane scheduling problem (QCSP), a work plan is generated for the quay cranes that are assigned to a vessel. Differing from berth allocation, the QCSP is solved shortly before the service process of a vessel starts. One reason is that the set of containers whose loading and unloading operations have to be scheduled on the cranes is not known until a vessel leaves its

previous port of call. Therefore, input data for the crane scheduling can be provided by vessel operators to a terminal's management only on a short-term basis. For the QCSP, the containers that have to be loaded and unloaded are considered as a set of tasks to be scheduled on the cranes. The tasks describe the granularity in which the workload of a vessel is considered in a QCSP model. As illustrated in Fig. 5, a task can be defined by the loading and unloading operations of containers of a bay area, a single bay, a container stack, a container group, or an individual container, respectively [116–120]. Precedence relations among tasks can be given to ensure that unloading operations precede loading operations and to represent the stacking of containers as defined by a stowage plan. A solution to the problem, called a *QC schedule*, defines a starting time for every task on a crane. Usually, the minimization of the makespan of the QC schedule is pursued, because a minimum makespan corresponds to a shortest possible vessel handling time [100,117,119]. Another objective of crane scheduling is the

maximization of crane utilization [116,121]. To avoid the crossing of cranes in a schedule and to comprise the compliance with safety margins between adjacent cranes, the QCSP requires so-called interference constraints [100,119,122,123]. Figure 6 shows a crane schedule for a vessel with 10 bays and 18 container groups that is served by 3 cranes. Here, the cranes have to keep a safety margin of two bays at all times. The latest completion time among all tasks is 233 time units, which corresponds to the makespan of the schedule and to the handling time of the vessel.

A Review of Models Proposed in the Literature

Quay crane scheduling models are distinguished into models defining tasks to be scheduled on the basis of bay areas, single bays, container groups, container stacks, or individual containers. In the simplest case, tasks refer to bay areas, where each area is exclusively served by one QC. If the bay areas are nonoverlapping, the problem is to partition the bays of a vessel such that the

Figure 5. Storage location structure of a vessel (a) and a bay (b).

Figure 6. An example of a quay crane schedule.

workload is uniformly distributed among the cranes [116,121]. The partitioning ensures the noncrossing of the rail-mounted QCs. In addition, safety margins can be incorporated to avoid that adjacent cranes come too close to each other in a solution [122,124].

A better workload distribution is often achievable, if tasks are defined by single bays instead of bay areas. Since the operating areas of cranes can overlap, a noncrossing constraint must be incorporated to ensure feasibility of schedules. Except for the early models of Daganzo [125] and Peterkofsky and Daganzo [126], noncrossing constraints are a standard in crane scheduling models for complete bays [65,100,117,127–133]. Safety margins are additionally incorporated in the models of Liu *et al.* [100] and Choo *et al.* [133]. The pursued objective is the minimization of the schedule makespan [127,100,117,128–131,133], the minimization of the total weighted completion time of tasks [132] or the minimization of the crane travel time [65]. In the models of Daganzo [125], Peterkofsky and Daganzo [126], and Choo *et al.* [133] the service is planned for several vessels simultaneously and the pursued objective is the minimization of the total weighted completion time of vessels.

Enabling the cranes to share the workload of bays is the most typical feature of models where tasks are defined by container groups. Models for crane scheduling with container groups incorporate precedence relations among tasks to ensure that certain container groups are unloaded before other groups are loaded and to respect the stacking of containers within a bay [12,119,123,134–140]. Except for Ng and Mak [137], who consider only the noncrossing of cranes, all models for crane scheduling with container groups respect the noncrossing and safety margins to avoid crane interference. All studies propose the minimization of the schedule makespan as an objective. When cranes are scheduled for several vessels in parallel, minimization of the total finishing time of QCs and minimization of total vessel tardiness can also serve as objectives [136].

Stack-based crane scheduling has been investigated by various authors [118,141–146]. In these studies, a single

crane is considered that processes the container stacks of one bay. The focus is on the parallelization of loading and unloading of different stacks in a crane schedule. This so-called *crane double cycling* can considerably decrease the service time of a vessel bay. In Zhang and Kim [146] the consideration is extended toward the handling of hatches that cover adjacent stacks of containers. In the model of Meisel and Wichmann [120] crane scheduling is investigated on the basis of single containers. Besides the realization of crane double cycling in a schedule, reshuffled containers can be repositioned within a bay instead of temporarily unloading them. Such internal reshuffles further accelerate the service of a vessel bay. All the mentioned studies pursue a minimization of the schedule makespan.

Quay crane scheduling issues have been furthermore incorporated in some advanced approaches for stowage planning, horizontal transport operations planning, and yard crane scheduling [41,27,147–151].

Two Examples of Models Proposed in the Literature

The following sections present two models for QC scheduling. The model of Goodchild and Daganzo [143] is remarkable because it incorporates crane double cycling into the service operations planning for a crane at a bay of a container vessel. The model of Bierwirth and Meisel [123] considers multiple QCs that jointly serve one container vessel. This model is taken up here, because it contains elaborate constraints for avoiding crossing of cranes and for ensuring safety margins between adjacent cranes.

A Model for Quay Crane Scheduling with Container Stacks. The QCSP for container stacks has been formulated by Goodchild and Daganzo [143]. In this problem, a single bay of a container vessel is considered. One QC must unload the container stacks in the bay and load new containers into the cleared stack. The set of stacks is denoted by S . For each stack $i \in S$, the number of containers to unload is given by u_i and the number of containers to load is given by l_i .

The decisions to be made concern finding an order for the unloading operations and the loading operations. These decisions are represented by binary variables x_{ij} , 1 if $i \in S$ is unloaded before $j \in S$ and 0 otherwise, and y_{ij} , 1 if $i \in S$ is loaded before $j \in S$ and 0 otherwise. Furthermore, FU_i denotes the completion time for unloading stack i and FL_i denotes the completion time for loading stack i . The objective is the minimization of the handling time w of the considered bay, which corresponds to the maximum completion time among all operations. This goal is achieved through simultaneously performing loading and unloading operations, which means to apply crane double cycling in a solution whenever possible.

The following assumptions are made for the problem:

- No hatch covers separate above-deck and below-deck containers in the bay.
- The processing time for loading or unloading a stack is directly proportional to the number of containers to transship.
- Loading or unloading a stack is performed continuously without any interruption, that is, the operations are performed nonpreemptive.
- Crane operations cannot lead to an instable load configuration of the vessel.

The QCSP for container stacks is formulated as follows:

$$\text{minimize } w \quad (27)$$

s.t.

$$w \geq FL_i \quad \forall i \in S, \quad (28)$$

$$FL_i - FU_i \geq l_i \quad \forall i \in S, \quad (29)$$

$$FU_i - FU_j + M \cdot x_{ij} \geq u_i \quad \forall i, j \in S, \quad (30)$$

$$FU_j - FU_i + M \cdot (1 - x_{ij}) \geq u_j \quad \forall i, j \in S, \quad (31)$$

$$FL_i - FL_j + M \cdot y_{ij} \geq l_i \quad \forall i, j \in S, \quad (32)$$

$$FL_j - FL_i + M \cdot (1 - y_{ij}) \geq l_j \quad \forall i, j \in S, \quad (33)$$

$$FU_i \geq u_i \quad \forall i \in S, \quad (34)$$

$$x_{ij}, y_{ij} \in \{1, 0\} \quad \forall i, j \in S. \quad (35)$$

The objective (27) is to minimize the handling time of the bay, which is determined (28) by the maximum completion time of all loading operations of stacks. Constraints (29) ensure that a stack is loaded after it has been unloaded. Constraints (30) and (31) ensure that stacks are unloaded one after the other, where either stack i is unloaded before stack j if $(x_{ij} = 1)$ or j is unloaded before i ($x_{ij} = 0$). Accordingly, constraints (32) and (33) handle the loading operations of stacks. Constraints (34) and (35) define feasible domains of decision variables.

A Model for Quay Crane Scheduling with Container Groups.

In the QCSP for container groups, a set of tasks $\Omega = \{1, 2, \dots, n\}$ and a set of QCs $Q = \{1, 2, \dots, q\}$ are given. Each task $i \in \Omega$ represents a loading or unloading operation of a certain container group. The tasks have individual processing times p_i and bay positions l_i . In addition, dummy tasks 0 and $T = n + 1$ with processing times $p_0 = p_T = 0$ are given to indicate the start and end of the service of the vessel. Further task sets are defined by $\Omega^0 = \Omega \cup \{0\}$, $\Omega^T = \Omega \cup \{T\}$, and $\overline{\Omega} = \Omega \cup \{0, T\}$. Precedence relations may exist between pairs of tasks that are located within the same bay. Let Φ denote the set of precedence constrained task pairs. Furthermore, let $\Psi \supseteq \Phi$ denote the set of all task pairs for which it is known in advance that they cannot be processed simultaneously. For each crane $k \in Q$ a ready time r^k and an initial bay position l_0^k are given. Without loss of generality, it is assumed that the cranes are indexed sequentially according to their initial positioning alongside the vessel. All QCs can move between two adjacent bays in an identical travel time $\hat{t} > 0$. The travel time of QC k to traverse from its initial position l_0^k to l_j ($j \in \Omega$) is defined as $t_{0j}^k = \hat{t} \cdot |l_0^k - l_j|$. The travel time between bay positions l_i and l_j ($i, j \in \Omega$) is defined as $t_{ij} = \hat{t} \cdot |l_i - l_j|$. If i or j or both belong to $\{0, T\}$ the travel time is set to $t_{ij} = 0$. It is supposed that cranes are not allowed to cross each

other and that they have to keep a safety margin δ , measured in units of bays. The problem is to find completion times c_i for all tasks $i \in \overline{\Omega}$ with respect to the constraints such that the completion time c_T of the final task T (i.e., the makespan) is minimized.

The assumptions of the QCSP with container groups are as follows:

- Container groups are predefined from given stowage plans.
- Processing of tasks is nonpreemptive.
- All QCs show an identical, deterministic transshipment productivity. For this reason fixed processing times are given for the tasks.
- Crane operations cannot lead to an instable load configuration of the vessel.
- There is sufficient space beside the vessel to place idle QCs outside of the vessel area.

The QCSP for container groups is formulated as follows:

$$\text{minimize } c_T \quad (36)$$

s.t.

$$\sum_{j \in \Omega^T} x_{0j}^k = 1 \quad \forall k \in Q, \quad (37)$$

$$\sum_{j \in \Omega^0} x_{jT}^k = 1 \quad \forall k \in Q, \quad (38)$$

$$\sum_{k \in Q} \sum_{j \in \Omega^T} x_{ij}^k = 1 \quad \forall i \in \Omega, \quad (39)$$

$$c_i \geq 0 \quad \forall i \in \overline{\Omega}, \quad (50)$$

$$x_{ij}^k \in \{0, 1\} \quad \forall i, j \in \overline{\Omega}, \forall k \in Q, \quad (51)$$

$$z_{ij} \in \{0, 1\} \quad \forall i, j \in \Omega. \quad (52)$$

The objective (36) pursued is to minimize the handling time of the vessel. It is defined by the completion time of dummy task T because every crane is forced to visit this task after processing its assigned nondummy tasks. Constraints (37) and (38) ensure that every QC starts with the initial dummy task 0 and ends up with the final dummy task T . Constraints (39) ensure that each nondummy task is processed exactly once. Constraints (40) ensure that every nondummy task has a preceding task and a succeeding task. The completion times of the tasks are computed in constraints (41) where M is again a sufficiently large positive number. Note that for $j = T$ the makespan is computed by this constraint. The precedence relations are included in constraints (42) with respect to the task completion times. Constraints (43) and (44) set the variables z_{ij} . On this basis the nonsimultaneity condition of tasks is represented in constraints (45). Constraints (46–48) ensure that cranes do not cross and that safety margins between adjacent cranes are not violated. For this purpose,

the constraints insert buffer time between the processing of two tasks that enables a safe movement and repositioning of cranes. More formally, Δ_{ij}^{vw} denotes the minimum time span to elapse between the processing of two tasks i and j , if processed by QCs v and w respectively. For all combinations of tasks $i, j \in \Omega$ and QCs $v, w \in Q$ the minimum time span to elapse between the processing of the tasks is defined as

$$\Delta_{ij}^{vw} = \begin{cases} (l_i - l_j + \delta_{vw}) \cdot \hat{t}, & \text{if } v < w \text{ and } i \neq j \\ \quad \text{and } l_i > l_j - \delta_{vw}, \\ (l_j - l_i + \delta_{vw}) \cdot \hat{t}, & \text{if } v > w \text{ and } i \neq j \\ \quad \text{and } l_i < l_j + \delta_{vw}, \\ 0, & \text{otherwise.} \end{cases} \quad (53)$$

In the first case of Equation (53), crane v is deployed at a lower quay position than crane w ($v < w$), whereas the second case considers the reverse. A positive buffer time is required if the tasks are located at bays that are too close together to be processed simultaneously by the cranes. This is determined through δ_{vw} , which is the smallest allowed difference between the bay positions of cranes v and w , that is, $\delta_{vw} = (\delta + 1) \cdot |v - w|$. Otherwise, no buffer time is required between the processing of the tasks, which is indicated through setting $\Delta_{ij}^{vw} = 0$ in the third case of Equation (53). Θ denotes the set of all combinations of tasks and QCs that potentially lead to crane interference. It can be defined as

$$\Theta = \{(i, j, v, w) \in \Omega^2 \times Q^2 \mid (i < j) \wedge (\Delta_{ij}^{vw} > 0)\}. \quad (54)$$

Owing to the symmetry of the temporal distances Δ_{ij}^{vw} the consideration can be restricted to pairs of tasks with $i < j$. Actually, a certain combination in Θ will cause interference only if its task-to-QC assignment is selected in the schedule. Since this is unknown in advance, every element of Θ must be treated by a constraint in the QCSP model. In constraints (46) those assignments of tasks to QCs are identified that are realized in the schedule. Here, $\sum_{u \in \Omega^0} x_{ui}^v = 1$ if and only if task i

is processed by QC v and $\sum_{u \in \Omega^0} x_{uj}^w = 1$ if and only if task j is processed by QC w . If both assignments take place, the left side reveals a value of two and the tasks are not allowed to be processed simultaneously, that is, either $z_{ij} = 1$ or $z_{ji} = 1$. In the case of $z_{ij} = 1$, constraints (47) insert the minimum temporal distance calculated by Equation (53) between the completion time of task i and the starting time of task j . The corresponding case of $z_{ji} = 1$ is handled in constraints (48). The ready times of QCs are handled in Equation (49) and the feasible domains of the decision variables are defined in Equations (50–52).

Discussion of the Models. The models presented approach crane scheduling in quite different ways. The model in the section titled “A Model for Quay Crane Scheduling with Container Stacks” is a pioneering one, because it incorporates crane double cycling into QC scheduling. Crane double cycling provides a cheap opportunity for decreasing vessel handling times of terminal operators. In Goodchild and Daganzo [144] the economic advantages of QC double cycling are proven in terms of increased crane productivity, berth utilization, and vessel utilization. Since the scope of the model is restricted to a single bay, it must be solved once for every bay of a vessel in order to produce work plans for the cranes. Even then, an appropriate allocation of bays to the cranes and the interaction of the cranes at a vessel have not been taken care of. These issues are the focus of QCSP models that schedule the complete handling operations of a vessel. The model in the section titled “A Model for Quay Crane Scheduling with Container Groups” enables to distribute the workload among the cranes assigned to a vessel and to schedule the tasks while considering precedence relations, crane movements, the noncrossing condition, and safety margins between cranes. Although the model considers practical issues of crane operations in high detail, it does not support crane double cycling in a schedule.

When it comes to solving the problems presented, an efficient solution method is available for the model in the section titled

“A Model for Quay Crane Scheduling with Container Stacks.” The problem formulation corresponds to a two-machine flow shop scheduling problem that can be solved to optimality using the rule of Johnson [152]. In contrast, the problem in the section titled “A Model for Quay Crane Scheduling with Container Groups” is an $\mathcal{NP}$ -hard parallel machine scheduling problem. To cope with the complexity, Bierwirth and Meisel [123] propose a branch-and-bound algorithm that searches a heuristically reduced solution space of the problem.

CONCLUSIONS

This article provides an overview of operational planning problems in seaport terminals. It describes the problems from a decision support perspective by outlining the decisions to make and the objectives that are typically pursued. For berth allocation, quay crane assignment, and quay crane scheduling, detailed literature surveys and examples of recent optimization models have been presented.

Despite the progress achieved in research on container terminal operations planning, there are several open issues that should be a subject of future research. A general need is to enhance models and solution methods to consider terminal operations in higher detail and to generate operational plans of higher quality. A particular need for research is found in a better integration of the decision fields. Many problems described above are closely interrelated. Often, the output of one planning problem serves as the input for another problem. For example, in stowage planning the positions of containers onboard a vessel are decided on and in quay crane scheduling the fastest possible way to accomplish the required loading and unloading operations is searched for. From an integration of these fields, stowage plans that support fast service operations of quay cranes can be generated.

A challenging field of research is to investigate dynamic and stochastic aspects of terminal operations. Little has been done

on robust optimization and stochastic programming in terminal operations planning although various sources of uncertainty exist, for example, from unpunctual arrivals of vessels, unknown destination ports for arriving transshipment containers, or breakdown of equipment. Inclusion of these aspects into the operational planning processes will be a valuable step toward more reliable terminal operations.

INTRODUCTION

Uncertainty is a pervasive feature of our world, and fields such as decision analysis and statistics provide methods to help us make decisions, forecasts, and inferences in the face of uncertainty. Our everyday language includes many terms that relate to the degree of uncertainty in a situation: for example, rain is unlikely today, the chances are good that a surgical procedure will be successful, the prospects for an improved economic situation are not favorable, and so on. As the mathematical language of uncertainty, probability theory provides a structure to quantify uncertainty. Probabilities are encountered in the media (e.g., the probability of rain this afternoon is 20%) and widely used in modeling.

Although probability forecasts are formulated and used extensively, very often they are never evaluated after the event or variable of interest is observed. Scoring rules provide such evaluations by giving a numerical score based on the probabilities and on the actual observation. For example, a probability of rain of 40% in a simple two-state setting of rain versus no rain will receive a higher score than a probability of 20% if it rains, and a lower score if it does not rain. In this manner, we can use scoring rules to compare the sources of the probabilities, which might be experts, models, or simply past data. The first scoring rule used on a regular basis was a quadratic rule developed

by Brier [1] to evaluate probabilistic weather forecasts. Indeed, weather forecasting is the area in which scoring rules have been used most extensively.

The presence of such an *ex post* evaluation using suitably designed scoring rules also provides *ex ante* incentives for careful formulation of probability forecasts. Much of the early development of scoring rules emphasized this *ex ante* role of scoring rules [e.g., [2–6]]. Attention was focused on strictly proper scoring rules, for which a forecaster can maximize his or her expected score only by honestly reporting the probabilities and also has the incentive to obtain further information to increase the accuracy of the probabilities. This *ex ante* motivation yields rules that reward probabilities that have good characteristics *ex post*, as we shall see. For a general discussion of scoring rules and reviews of the scoring rule literature, see Winkler [7] and Gneiting and Raftery [8].

We discuss some basic properties of scoring rules in the second section, focusing on the aspects related to *ex ante* incentives, and present some commonly encountered rules. In the next section, we turn to *ex post* evaluation, showing how some notions involving strictly proper scoring rules relate to *ex post* evaluation. The next two sections involve scoring rules with special characteristics, namely those that provide evaluations of probabilities relative to baseline distributions and those that take into account any ordering of the events of interest. A brief summary and discussion, including some connections with other fields, is presented in the final section.

STRICTLY PROPER SCORING RULES

We begin by considering the simplest possible situation, that of a single event A and its complement. Suppose that an expert is assessing a probability for A and is being evaluated with a scoring rule S . If a probability r is reported for A , then the score will be

$S(r, e)$, where $e = 1$ if A occurs and $e = 0$ if A does not occur. Furthermore, assume that the expert's best judgment is that the probability of A is denoted by p . Then the expected score is $S(r, p) = pS(r, 1) + (1 - p)S(r, 0)$. The scoring rule S is said to be *strictly proper* if

$$S(p, p) > S(r, p) \text{ for any } r \neq p. \quad (1)$$

To maximize the expected score with a strictly proper rule, the expert should set $r = p$, thereby reporting the probability honestly. The scoring rules discussed here are oriented such that a higher score is better. Some rules in the literature, such as the Brier score [1], are oriented with a negative score being better, in which case the expert should set $r = p$ to minimize the expected score. Rules such as the Brier score can be converted to a positive orientation by changing the sign of the score, so the focus on scores with a positive orientation here is not restrictive.

The expected score $S(p, p)$ for honest reporting from a strictly proper scoring rule is strictly convex, and conversely, a strictly proper scoring rule can be generated from any strictly convex function of p that is taken as the expected score function $S(p, p)$ for honest reporting [6]. Thus, there are an infinite number of rules satisfying Equation (1). Three commonly used rules are as follows:

Quadratic:

$$S(r, e) = 1 - 2(e - r)^2, \quad (2)$$

Logarithmic:

$$S(r, e) = \log[re + (1 - r)(1 - e)], \quad (3)$$

Spherical:

$$S(r, e) = [re + (1 - r)(1 - e)] / [r^2 + (1 - r)^2]^{1/2}. \quad (4)$$

These and any other strictly proper rules can be scaled as desired (e.g., to avoid negative scores), because any positive affine transformation of a strictly proper rule is itself strictly proper. Figure 1 shows $S(r, 1)$, $S(r, 0)$, and $S(p, p)$ for the quadratic scoring rule. Note that for this simple two-event setting, $S(r, 1)$ and $S(r, 0)$ are mirror images of each

Figure 1. (a) Score functions $S(r, 1)$ and $S(r, 0)$ and (b) expected score $S(p, p)$ under honest reporting for the quadratic scoring rule.

other, with $S(r, 1)$ increasing in r and $S(r, 0)$ decreasing in r .

With the general concept of a strictly proper scoring rule established for the case of a single event (and its complement), we next generalize to the case of a set of mutually exclusive and exhaustive events $\{A_1, \dots, A_k\}$, for which the expert's probabilities are given by the vector $\mathbf{p} = (p_1, \dots, p_k)$ and the reported probabilities are $\mathbf{r} = (r_1, \dots, r_k)$. With a scoring rule S , the expert's score is $S(\mathbf{r}, \mathbf{e}_i)$ if A_i occurs, where $\mathbf{e}_i$ is a vector with the i th element equal to 1 and the other elements all equal to 0. The expected score from the perspective of the expert is $S(\mathbf{r}, \mathbf{p}) = \sum_{i=1}^k p_i S(\mathbf{r}, \mathbf{e}_i)$, and the scoring rule is strictly proper if $S(\mathbf{p}, \mathbf{p}) > S(\mathbf{r}, \mathbf{p})$ for any $\mathbf{r} \neq \mathbf{p}$. Quadratic, logarithmic, and spherical

rules for this case are

$$S(\mathbf{r}, \mathbf{e}_i) = 2r_i - \sum_{j=1}^k r_j^2, \quad (5)$$

$$S(\mathbf{r}, \mathbf{e}_i) = \log r_i, \quad (6)$$

$$\text{and } S(\mathbf{r}, \mathbf{e}_i) = r_i / \left(\sum_{j=1}^k r_j^2 \right)^{1/2}, \quad (7)$$

respectively. Note that this setup could be used when we are considering a discrete distribution of a random variable, which could include a discretization of a continuous random variable into a set of intervals.

Finally, we present scoring rules for probability distributions of a continuous random variable $\tilde{x}$. Let p denote the expert's probability density function for $\tilde{x}$, and let r denote the corresponding reported density function. Then, for a scoring rule that gives a score $S(r, x)$ when $\tilde{x} = x$, the expert's expected score is $S(r, p) = \int_{-\infty}^{\infty} S(r, x)p(x)dx$. Quadratic, logarithmic, and spherical scoring rules in the continuous case are

$$S(r, x) = 2r(x) - \int_{-\infty}^{\infty} r^2(x) dx, \quad (8)$$

$$S(r, x) = \log r(x), \quad (9)$$

$$\text{and } S(r, x) = r(x) / \left(\int_{-\infty}^{\infty} r^2(x) dx \right)^{1/2}. \quad (10)$$

Our focus has been on strictly proper scoring rules, which have been developed with the goal of providing the expert with an incentive to report honestly. But if the expert is not well-informed with respect to the situation, reporting probabilities honestly may not mean reporting "good" probabilities. Not all probability forecasts are necessarily "good" forecasts. Fortunately, assuming honest forecasting, strictly proper scoring rules will reward forecasts by providing higher expected scores to forecasts for which p is closer to 0 or 1. To see how this works for the quadratic, logarithmic, and spherical rules that have been presented here, we note that they share an important characteristic: they are symmetric. In the single-event case, that means that the expected score

for an honestly reported probability of r is the same as the expected score for an honestly reported probability of $1-r$. As noted earlier, reporting $r = p$ under a strictly proper scoring rule results in an expected score function $S(p, p)$ that is strictly convex in p . This convexity, combined with the symmetry, means that $S(p, p)$ is minimized at $p = 0.5$ and increases as $p \rightarrow 0$ or $p \rightarrow 1$ from $p = 0.5$. These features of $S(p, p)$ are illustrated for the quadratic rule in Fig. 1. That means that under honest reporting, the expected score is higher for probability forecasts that are sharper, where sharpness refers to the degree that p is closer to 0 or 1. For example, a probability of 0 or 1 is perfectly sharp, whereas a probability of 0.5 admits a lot of uncertainty about the outcome.

To illustrate the incentives from strictly proper scoring rules for both honesty and sharpness, consider a decomposition of the expected score for the quadratic rule in the case of a probability for a single event. The expected score is $S(r, p) = p[1 - 2(1 - r)^2] + (1 - p)(1 - 2r^2)$. Expanding, adding and subtracting p^2 , and rearranging yields

$$S(r, p) = 1 - 2(p - r)^2 - 2p(1 - p). \quad (11)$$

The second term on the right-hand side of Equation (11) can be viewed as a penalty (because of the negative sign) for not setting $r = p$, and it thus provides an incentive for honesty. The last term is a penalty for lack of sharpness, because $p(1 - p)$ is maximized at $p = 0.5$ and decreases as $p \rightarrow 0$ or $p \rightarrow 1$. The best possible expected score is one, and dishonesty ($r \neq p$) or lack of perfect sharpness ($0 < p < 1$) will reduce the expected score. Other strictly proper rules (e.g., the logarithmic and spherical rules) can be decomposed in a similar manner.

Keep in mind that to maximize expected score, the expert has to report honestly, so attempting to have probabilities look sharp artificially (i.e., sharp reported probabilities that are not consistent with the expert's judgments) will decrease the expected score, not increase it. Note from Equation (11) that the sharpness term relates to the sharpness of p , not the sharpness of r . The primary

aspect of strictly proper scoring rules is to encourage honesty, and the nature of strictly proper scoring rules is such that honest reporting by experts who have sharper probabilities will yield higher expected scores than honest reporting by experts who have probabilities that are not so sharp. In the final analysis, then, strictly proper scoring rules reward both honesty and sharpness.

Strictly proper scoring rules differ in some characteristics. We will present different types of strictly proper rules in later sections and discuss some of their characteristics. As we shall see, not all strictly proper rules are symmetric in the sense discussed above, and in some cases it may be desirable to use a rule that is not symmetric. Another characteristic of note is that the logarithmic rule is the only rule for which the score depends only on the probability or density that has been assigned to the event or value of the variable that actually occurs. It does not depend on the probability or density assigned to other events or values. For example, if we consider scoring rules for k mutually exclusive and exhaustive events and event A_i occurs, the logarithmic score, $\log r_i$, depends only on r_i , whereas the quadratic score, $2r_i - \sum_{j=1}^k r_j^2$, depends on all of the probabilities $r_1, \dots, r_k$. This property, unique to the logarithmic rule when $k > 2$, is called *locality*, and it is consistent in spirit with the likelihood principle that plays a major role in statistics.

Although the quadratic, logarithmic, and spherical rules given above are the usual suspects when we think about scoring rules, they are special cases of two rich families of strictly proper scoring rules [9]. When probabilities for a set of k mutually exclusive and exhaustive events are reported, scores for the pseudospherical and power families are given by

$$S_\beta^S(\mathbf{r}, \mathbf{e}_i) = \frac{1}{\beta - 1} \left[\left(\frac{r_i}{E_{\mathbf{r}}(\mathbf{r}^{\beta-1})^{1/\beta}} \right)^{\beta-1} - 1 \right] \quad (12)$$

and

$$S_\beta^P(\mathbf{r}, \mathbf{e}_i) = \frac{r_i^{\beta-1} - 1}{\beta - 1} - \frac{E_{\mathbf{r}}(\mathbf{r}^{\beta-1}) - 1}{\beta}, \quad (13)$$

respectively, where $E_{\mathbf{r}}(\mathbf{r}^{\beta-1}) = \sum_{i=1}^k r_i(r_i^{\beta-1})$ and $-\infty < \beta < \infty$. When $\beta = 2$, Equations (12) and (13) yield the spherical and quadratic rules, respectively. When $\beta \rightarrow 1$, both families converge to the logarithmic rule.

In summary, the most important characteristic of scoring rules in an *ex ante* sense related to probability assessment is that they should be strictly proper, and there are many such rules from which to choose. If a rule is indeed strictly proper, then it should provide incentives for an expert to honestly report probabilities and to invest effort in an attempt to make those probabilities sharper. Such effort might be directed toward such things as gathering more data, using more powerful methods to analyze the data, and learning more about the processes affecting the events in question or about forecasts provided by others.

EX-POST EVALUATION WITH STRICTLY PROPER SCORING RULES

We shift now from the *ex ante* perspective of the previous section to consider the *ex post* evaluation of probability forecasts. For a given situation, we assume that an expert has probabilities that are based on the information available and consistent with the expert's best judgment. The *ex ante* viewpoint involves rules that provide incentives for the expert to attempt to come up with "good" probabilities and to report those probabilities honestly. Many of the characteristics discussed in the preceding section have counterparts when we consider their use for evaluation purposes.

As is the case with statistical analysis of data in general, a single observation is not very informative. To have a reliable evaluation (when comparing experts or models in terms of their probabilities, for example), we would like to have a large number of observations. Thus, instead of considering a given situation with a single probability or set of probabilities, we have a set of data consisting of many situations with different probabilities.

Suppose that we have a sample of probability forecasts and the corresponding observations for the occurrence of an event. For example, this might consist of probabilities of default for loans (generated by a model or assessed by a bank officer) or probabilities of rain for different days at a given location. First, we can look at all of the occasions in the data set for which a particular value of the reported probability r (say, 0.30) was used, and determine the relative frequency of occurrence of the event of interest on those occasions. Denote this relative frequency by f_r . With the quadratic scoring rule, the average score on all of the occasions with this value of r is $\bar{S}(r, f_r) = f_r[1 - 2(1 - r)^2] + (1 - f_r)(1 - 2r^2)$. *Ex ante*, the expected score from the perspective of the expert is a function of r and p , with p being known only to the expert. *Ex post*, the average score is a function of r and f_r , where we are able to observe f_r :

$$\bar{S}(r, f_r) = 1 - 2(f_r - r)^2 - 2f_r(1 - f_r). \quad (14)$$

Note that this is simply Equation (11) with f_r used in place of p .

The second term on the right-hand side of Equation (14) is a measure of *calibration*, which involves the correspondence between the reported probability and the relative frequency of occurrence of the event when that probability is used. If $f_r = r$, then the reported probabilities of r are perfectly calibrated. The more the relative frequency deviates from r , the worse the calibration is. The last term on the right-hand side of Equation (14) is a measure of *sharpness*, which is better as $f_r \rightarrow 0$ or $f_r \rightarrow 1$. Poorer calibration and less sharpness lead to lower average scores.

In data with reported probabilities and outcomes, different probabilities will be used on different occasions. The overall average score $\bar{S}$ for an expert is found by aggregating the average scores for the different values of r . If we let n_r represent the number of times a reported probability of r is used in the data set and let $n = \sum_r n_r$ represent the overall sample size, the overall average score can be

expressed as

$$\begin{aligned} \bar{S} &= \sum_r (n_r/n) \bar{S}(r, f_r) \\ &= 1 - 2 \sum_r (n_r/n) (f_r - r)^2 \\ &\quad - 2 \sum_r (n_r/n) f_r (1 - f_r). \end{aligned} \quad (15)$$

The first summation on the right-hand side of Equation (15) is an overall measure of calibration for the data set, and the second summation is an overall measure of sharpness. This decomposition into calibration and sharpness components can be generalized beyond the quadratic rule to any strictly proper scoring rule [10].

One convenient way to think about calibration and sharpness is to think of the probability assessment process for a single event as a two-step process. First, the expert puts forecast situations in equivalence classes, or “boxes,” such that the expert feels that the events in a given box have roughly the same probability of occurrence. Second, the expert assigns numbers (probability values) to the boxes. Calibration is then an evaluation of how well the expert assigns the numbers. Sharpness, on the other hand, is unrelated to the probability values. Instead, it measures how effective the expert is in creating boxes for which the relative frequency of occurrence of the events is close to 0 or 1. This is unlikely to be the way an expert really thinks about the forecasting process, but it is a convenient way to emphasize key differences between calibration and sharpness. For one thing, we can always attempt to correct for miscalibration. If an expert always gives probabilities that are too high, for example, a decision maker using those probabilities can reduce reported probabilities from that expert. Correcting for poor sharpness is a much trickier business.

We have illustrated the notion of decomposition of an average score using the quadratic scoring rule, but the same idea can be applied to other rules. Also, an *ex post* average score or an *ex ante* expected score can be decomposed in different ways. The decomposition into terms measuring calibration and sharpness is the most frequently

used decomposition, and it is arguably the most important decomposition. Gneiting and Raftery [8] comment that “the goal of probabilistic forecasting is to maximize the sharpness of the (probabilities) subject to calibration.” Although that seems reasonable, we feel that in reported evaluations, too much emphasis is typically given to calibration and not enough to sharpness.

Ex post evaluation with strictly proper scoring rules involves most of the same ideas encountered in the role of scoring rules in terms of *ex ante* incentives. *Ex ante* incentives for honesty translate into *ex post* evaluations of calibration, and *ex ante* measures of sharpness based on the probabilities translate into *ex post* measures based on the relative frequencies of occurrence of the events of interest for given probability values (given boxes). The use of scoring rules and their decompositions to evaluate probabilities *ex post* can be thought of as exploratory data analysis. Such evaluations can be used to compare experts or models. In the case of a single expert or model, they can be used to learn more about that expert’s or model’s characteristics and abilities as a probability forecaster. Feedback can also help the expert understand his or her own characteristics as a probability forecaster and attempt to improve them in the future.

SCORING RULES WITH BASELINE DISTRIBUTIONS

Scoring rules such as the quadratic, logarithmic, and spherical rules given earlier can be thought of as providing an “absolute” evaluation of probabilities. Often, we would like to have a relative evaluation by comparing how good a probability or probability distribution is, relative to some baseline. When assessing probabilities of rain, for example, it is easier to get a high score in a location where rain seldom occurs than it is in a location where it rains reasonably often. Does that mean that the probability forecasts in the drier area are better?

As noted earlier, the most commonly used scoring rules are symmetric in the sense that any permutation of the labels on the events

and their associated probabilities does not change the expected score. One implication of this symmetry, when combined with the convexity of the expected score function, is that the expected score is minimized for a uniform distribution that gives a probability of $1/k$ to each event in the k -event case. Thus, these scores are implicitly being evaluated relative to a uniform baseline distribution.

To avoid comparison with a uniform distribution, we could consider the percentage improvement in average scores over the scores for a baseline distribution. In assessing a probability of rain, for example, we might use climatology, which is the long-term relative frequency of rain in a given location at a specific time of year, as a baseline. However, a percentage improvement in the score over the baseline, which is called a skill score, is not strictly proper. For a strictly proper rule with a baseline distribution that is not uniform, we can choose a desired convex expected score function and generate a strictly proper rule that yields that expected score function [11]. For example, we might choose a function that is minimized at what might be viewed as a “least skillful” forecast. In forecasting rain, climatology might be considered “least skillful” among forecasts that seem reasonable, since it just involves looking up some past data and does not require any weather-forecasting expertise. In contrast, although a uniform distribution requires no expertise, it may not seem at all reasonable, as in the case of a dry location with a very low climatological relative frequency of rain.

Asymmetric rules can be generated from symmetric rules. For example, in the single-event case for which it is felt that the expected score with honest reporting should be minimized at a probability of q , we can take any symmetric strictly proper scoring rule S and create a new rule $S^*(r, e|q) = [S(r, e) - S(q, e)]/T(q)$, where $T(q) = S(1, 1) - S(q, 1)$ if $r \geq q$ and $S(0, 0) - S(q, 0)$ if $r \leq q$.

More generally, the families of scoring rules given by Equations (12) and (13) can be generalized to pseudospherical and power families of strictly proper scoring rules that allow for the incorporation of baseline distributions [9]. If the baseline

Figure 2. (a) Score functions $S(\mathbf{r}, \mathbf{e}_1|\mathbf{q})$ and $S(\mathbf{r}, \mathbf{e}_2|\mathbf{q})$ and (b) expected score $S(\mathbf{p}, \mathbf{p}|\mathbf{q})$ under honest reporting for the power scoring rule with $\beta = 2$ and $\mathbf{q} = (0.2, 0.8)$.

distribution for a set of k mutually exclusive and collectively exhaustive events is denoted by $\mathbf{q} = (q_1, \dots, q_k)$, then we can define the pseudospherical and power families of scoring rules with baselines as follows:

$$S_\beta^S(\mathbf{r}, \mathbf{e}_i|\mathbf{q}) = \frac{1}{\beta - 1} \left[\left(\frac{r_i/q_i}{E_{\mathbf{r}}[(\mathbf{r}/\mathbf{q})^{\beta-1}]} \right)^{\beta-1} - 1 \right] \quad (16)$$

and

$$S_\beta^P(\mathbf{r}, \mathbf{e}_i|\mathbf{q}) = \frac{(r_i/q_i)^{\beta-1} - 1}{\beta - 1} - \frac{E_{\mathbf{r}}[(\mathbf{r}/\mathbf{q})^{\beta-1}] - 1}{\beta}, \quad (17)$$

where $E_{\mathbf{r}}[(\mathbf{r}/\mathbf{q})^{\beta-1}] = \sum_{i=1}^k r_i(r_i/q_i)^{\beta-1}$ and $-\infty < \beta < \infty$. These scoring rules are scaled so that they yield scores of 0 when $\mathbf{r} = \mathbf{q}$. Thus, a positive score represents improvement over the baseline and a negative score indicates a forecast worse than the baseline. (The expert's *expected* score with honest reporting is positive except at $\mathbf{r} = \mathbf{q}$, where it is 0.) As with Equations (12) and (13), $\beta = 2$ corresponds to spherical and quadratic rules, respectively, in Equations (16) and (17), and both families converge to a logarithmic rule when $\beta \rightarrow 1$. Figure 2 shows $S_\beta^S(\mathbf{r}, \mathbf{e}_1|\mathbf{q})$, $S_\beta^S(\mathbf{r}, \mathbf{e}_2|\mathbf{q})$, and $S(\mathbf{p}, \mathbf{p}|\mathbf{q})$ for the power scoring rule with $\beta = 2$.

The consideration of baseline distributions provides a relative evaluation as opposed to an absolute evaluation, and relative evaluations are often of great interest. In addition, evaluations with baseline distributions can be useful in evaluating probabilities (and evaluating the forecasters providing the probabilities) that are made under different circumstances. For example, if one weather forecaster assesses probabilities of rain in a very dry climate (say, with a climatology of 0.05) and another forecaster assesses probabilities in a more moist climate (climatology 0.40), then it is much easier for the first forecaster to obtain higher scores in an absolute evaluation. This is because of the fact that the first forecaster is able, on average, to make sharper forecasts. If we use a relative evaluation with climatology as the baseline, then we are comparing the two forecasters in terms of how effective they are at improving upon a forecast based solely on climatology, thereby adjusting for the differences in the forecast situations. While not perfect, this will tend to even the playing field somewhat and make for fairer comparisons.

SCORING RULES THAT ARE SENSITIVE TO DISTANCE

In some situations, the events of interest are ordered. For example, in a soccer match, a team can win, lose, or tie. A win is better than a tie, which in turn is better than a loss,

so there is an ordering. If we are giving probabilities for $\tilde{x}$, the amount of rain in inches on a given day, we might assess probabilities for $\tilde{x} = 0$, $0 < \tilde{x} \leq 0.5$, $0.5 < \tilde{x} \leq 1$, and $\tilde{x} > 1$. These four events are ordered. The scoring rules for multiple events, discussed in the preceding sections, ignore any ordering. Suppose that two experts report probabilities of (0.3, 0.4, 0.2, 0.1) and (0.3, 0.1, 0.2, 0.4). If there is no rain, then the experts will receive the same score. They both gave a probability of 0.3 for the event that occurred, and they gave probabilities of 0.4, 0.2, and 0.1 for the other three events. The fact that the latter three probabilities were in different orders does not affect the score because the scoring rule does not take ordering of the events into account. Some might argue that the first expert gave more probability on the event closest to the event that occurred and should therefore receive a higher score. Scoring rules have been developed that would take ordering into account in this way, and we say that such rules are sensitive to distance. Informally, this means that for the probability not assigned to the event that occurs, a higher score will result if more probability is given to events closer to the event that occurs and less probability to “more distant” events.

The first strictly proper sensitive-to-distance scoring rule was a quadratic rule called the *ranked probability score* [12]: $S(\mathbf{r}, \mathbf{e}_i) = -\sum_{j=1}^{i-1} R_j^2 - \sum_{j=i}^{k-1} (1 - R_j)^2$, where $R_j = \sum_{l=1}^j r_l$ is a cumulative probability. By connecting the score to cumulative probabilities, the rule is able to take sensitivity to distance into consideration. As probability “moves” from events more distant from the event that occurs to events closer to the event that occurs, the cumulative probabilities change accordingly and result in an increase in the score.

The same idea that is used to generate the ranked probability score from the quadratic score can be used to obtain a sensitive-to-distance scoring rule S^* based on any strictly proper rule S for a single event and its complement:

$$S^*(\mathbf{r}, \mathbf{e}_i) = \sum_{j=1}^{i-1} S(R_j, 0) + \sum_{j=i}^{k-1} S(R_j, 1). \quad (18)$$

The corresponding expected score is $S^*(\mathbf{r}, \mathbf{p}) = \sum_{i=1}^{k-1} [P_i S(R_i, 1) + (1 - P_i) S(R_i, 0)]$, using a vector $\mathbf{P}$ of cumulative probabilities $P_j = \sum_{l=1}^j p_l$ based on $\mathbf{p}$. Note that Equation (18) can be used to generate new pseudospherical and power families of strictly proper scoring rules, with or without baseline distributions [13]. If baseline distributions are used, they will be expressed in cumulative form, with a vector $\mathbf{Q}$ of cumulative probabilities $Q_j = \sum_{l=1}^j q_l$ representing the cumulative baseline distribution.

It is important to mention that properties of the scoring rule S in Equation (18), other than the fact that it is strictly proper, are not necessarily inherited by S^* . For example, if S is logarithmic, S^* will not inherit the property of locality mentioned earlier. The score is based on the cumulative probabilities $R_1, \dots, R_{k-1}$, so it clearly depends on more than just r_i . Also, if S^* is determined from Equation (18) using a symmetric, strictly proper S without a baseline distribution, then the expected score $S^*(\mathbf{p}, \mathbf{p})$ is minimized at $\mathbf{p} = (0.5, 0, \dots, 0, 0.5)$. That is, if a baseline distribution is not chosen, the default baseline distribution is $(0.5, 0, \dots, 0, 0.5)$, not $(1/k, \dots, 1/k)$, and the score for a uniform distribution will not be the same for all events because the ordering of the events is relevant and some events are more distant from others. Note that the default baseline distribution of $(0.5, 0, \dots, 0, 0.5)$ for S^* translates to $(0.5, \dots, 0.5)$ when expressed in terms of the cumulative probabilities $(R_1, \dots, R_{k-1})$. Since the relevant probabilities are cumulative in a score that is sensitive to distance, the baseline distribution is uniform in the cumulative probabilities. Furthermore, this distribution will give the same score S^* regardless of which event occurs, because $R_j = 0.5$ in each of the $S(R_j, 0)$ and $S(R_j, 1)$ terms in Equation (18).

Commonly encountered scoring rules ignore any ordering of the events. When the events of interest are ordered, however, the ordering may be important in terms of the underlying real-world situation. For instance, with forecasts of returns on an investment, high probabilities for values that are not identical to the returns that actually occur but are close to those returns would

seem to be more valuable for investment purposes than high probabilities for values that are quite distant from the actual returns. In such a setting, a scoring rule that is sensitive to distance might provide incentives and an *ex post* evaluation that are more consistent with the decision making problem.

SUMMARY AND DISCUSSION

Probability forecasts are important inputs to quantify uncertainty in inferential and decision making problems. It is therefore important to have appropriate incentives for careful formulation of probability forecasts and to have measures to evaluate the forecasts once the uncertainty is resolved and we see what actually happens. Those are exactly the roles that are played by scoring rules. In particular, strictly proper scoring rules provide incentives for making good forecasts (i.e., sharp forecasts) and reporting them honestly. In terms of *ex post* evaluation, the incentive for honest reporting *ex ante* translates into measures of the calibration of the forecasts, and given good calibration, sharper forecasts will earn higher scores on average. A few scoring rules tend to be used most often, but rich families of strictly proper scoring rules have been developed. Beyond the basic rules, there are options that add more flexibility while maintaining the strictly proper nature of the rules. Some rules allow the evaluation of probabilities relative to a chosen baseline distribution. Among other things, this makes scores for probabilities made in different situations more comparable. Other rules take into account any ordering of the events and are sensitive to distance in the sense of giving higher scores to probability distributions assigning higher probabilities to events near the event that occurs, all other things being equal. This feature is relevant when being “close” with the probability forecast can lead to better decisions or inferences.

How might a user choose a scoring rule in a given situation? Among the basic rules, some have different properties from others and different rules can lead to different scores and different rankings of experts [14]. Thus,

the choice of a rule might depend on how one feels about those properties and about the situation at hand. For example, with probabilistic answers for a multiple-choice test, the locality property of the logarithmic rule might have strong appeal. At the same time, the possibility of a score of negative infinity with the logarithmic score is a potential concern; some claim that the logarithmic rule has undesirable properties [15], and in certain settings, locality becomes less important. For example, in a two-event setting, all rules satisfy locality, and in a setting where sensitivity to distance is considered important, a sensitive-to-distance logarithmic rule no longer has the locality property. There is no general agreement on a single “best” rule for all situations.

The use of a scoring rule that involves the choice of a baseline distribution depends on whether a relative evaluation is desired and whether there is a specific baseline distribution against which to compare probabilities. An important thing to keep in mind is that using the basic rules without choosing a baseline distribution means that probabilities are being evaluated relative to the default distribution, which is a uniform distribution. Another choice when events are ordered is whether to use a rule that is sensitive to distance, and this choice is related to whether giving higher probabilities to events close to the event that occurs is viewed as important for the situation at hand.

What about practical issues in using the rules? The use of the rules *ex post* to evaluate probabilities is straightforward, just involving the computation of scores using the formula for any scoring rule that is chosen. Scores can then be used as feedback to enable experts and modelers to see their performance and perhaps learn from it. The use of scoring rules *ex ante* means that they should be part of a general probability assessment process that might include some training regarding probability if necessary. For many experts, the connection of the scoring rule formulas with the incentives is too opaque to make it valuable to dwell on the formulas. Discussing the incentives in an intuitive fashion is generally more effective. One option for relatively simple cases (e.g., a probability

for a single event) is to present the possible scores in graphical or tabular form.

The incentive to maximize expected score with strictly proper scoring rules is probably reasonable in most cases. In the context of thinking of the expert as wanting to maximize expected utility, it implies that the utility function is linear in the score (or linear in money if the score is translated into a monetary reward). If the expert's utility function $U(S)$ for the score is known, a modification of the score to $S' = U^{-1}(S)$ with a strictly proper S will adjust for U , since $U(S') = U[U^{-1}(S)] = S$, and will thereby encourage honest reporting. A practical problem with this is that we are not likely to know U , and eliciting it from the expert is not easy. In many cases, we feel that the importance of the score is probably not large enough to cause major violations of such linear utility due to risk aversion or risk taking, for example. However, if there are other stakes related to the probability forecasts, those stakes might cause significant shifting of the probabilities away from honest reporting. For example, if the situation is viewed as a contest against other experts (rightly or wrongly), the consideration of strategic play might lead the expert to give more extreme probabilities (i.e., probabilities closer to and often equal to 0 or 1) than justified by the expert's best judgments, in order to try to win the contest [16]. In most cases, however, we would expect that experts will try to come up with the best set of probabilities given the information that is available to them, and will not think strategically. In any event, strictly proper scoring rules can always be used for *ex post* evaluation purposes, and any hedging of reported probabilities can be expected to lead to lower average scores.

In closing, we note that work on scoring rules has interesting connections to other fields. Scoring rules are closely connected to decision theory/decision analysis. A decision maker may hire an expert to report probabilities for events related to the decision and might like to tailor a scoring rule to the decision-making problem, in the spirit of Savage's "share of the business" notion [6]. The expert's reported probabilities can

be viewed as new information by the decision maker, and connections between scores and the value of that information are of interest. These notions are related to the literature on incentives and mechanism design in economics and especially to agency theory. On a different tack, expected scores from strictly proper scoring rules are related to information measures from signal processing and information theory [9]. For example, the expected score for honest reporting under a logarithmic scoring rule is the negative Shannon entropy of the expert's probability distribution $\mathbf{p}$ and is the Kullback–Leibler divergence of $\mathbf{p}$ with respect to $\mathbf{q}$ if the baseline distribution $\mathbf{q}$ is chosen. Finally, extensive experimental work by psychologists has investigated the degree to which individuals' probability assessments are well calibrated and has led to various theories of the calibration of subjective probabilities [17]. Judgments about others' probabilities are important in competitive situations, and economics and psychology are both relevant for this issue. Given the importance of probability forecasts in decision modeling and statistics as well as the connections with these different (and somewhat disparate) fields, we expect the interest in scoring rules and the application of such rules in practice to grow.

SEARCH GAMES

SHMUEL GAL
Department of Statistics,
University of Haifa,
Haifa, Israel

The first significant contribution to operations research in the area of searching is the work of Koopman and his colleagues “Search and Screening” [1]. The work in these early years of search theory emphasized the problem of optimal distribution of effort spent in search. That topic is the main subject of the classic work of Stone [2], “Theory of Optimal Search,” which was awarded the 1975 Lanchester Prize by the Operations Research Society of America. The early work on Search Theory has been surveyed in Ref. 3. The later survey [4] shows how the determination of search trajectories has come to be studied more extensively.

The present article is focused on *search games* with players that move along continuous trajectories. (Many interesting search games of discrete nature, not covered by our article, can be found in the further reading list.) These continuous search games were introduced by Isaacs [5] in the last chapter of his book and were developed by Gal [6]. That work, and the updated version by Alpern and Gal [7], has stimulated much research, with applications in computer science, economics, and biology. The present article gives an overview of the area of search games including some recent development in this area.

A situation of “hide and seek” is quite common, ranging from children’s play to military conflicts. This situation is analyzed as a two-person zero-sum game which is called a *search game*. Such a game is characterized by a search space Q which is either a compact set in a Euclidean space or an unbounded connected set, for example, the real line. The searcher usually starts moving from a specified point O called the *origin* but choosing the starting point arbitrarily is also considered. It is assumed that the searcher is free

to choose any continuous trajectory inside Q , subject to a maximal velocity constraint which is normalized to 1. The hider can be either stationary or mobile. It will always be assumed that neither the searcher nor the hider has any knowledge about the movement of the other player until their distance apart is less than or equal to the discovery radius r and at this very moment, capture occurs. The discovery radius r is assumed to be small with respect to the dimension of Q . For one-dimensional sets, r is usually assumed zero. A search trajectory will be denoted by S and a hiding trajectory by H (a single point if the hider is immobile). The cost function (payoff to the maximizing hider) $c(S, H)$, is the time spent until the hider is found (the search time). A mixed strategy s (or h) of the searcher (or hider) is a probability measure on the set of the searcher’s (or hider) pure strategies. To rigorously present such strategies, one has to introduce a substantial amount of measure-theoretic machinery for these sets. Such a construction is presented in Ref. 6 including the result that $c(S, H)$ is Borel measurable in both variables, so that we can define the payoff c in the case that the searcher uses s and the hider uses h as the expected value of c with respect to the product measure $s \times h$:

$$c(s, h) = \int c(S, H) d(s \times h).$$

The existence of a value, v , (minimax theorem) for such problems, and an optimal searcher mixed strategy are established in Refs 6 and 8. (An optimal hiding strategy need not exist, only ε -optimal strategies always exist.) The existence theorem holds for both, immobile and mobile hider.

IMMOBILE HIDER

Searching a Graph

Assume that the search space Q is a finite connected graph in which each arc has a given length. The sum of these lengths will

be denoted by μ , called the *total length of the graph*. The graph Q can be viewed as a metric space, where the distance $d(.,.)$ between any two points (not just nodes) is the length of the shortest path between them. A pure strategy for the hider is simply a (hiding) point H in Q , which can be a node or a point on one of the arcs. A pure strategy $S = S(t)$ for the searcher is a continuous trajectory in Q with speed 1, that is, a function satisfying $d(S(t), S(t')) \leq |t - t'|$, for all $t, t' \geq 0$. The payoff c corresponding to pure strategies S and H is the search time $c(S, H) = \min\{t : S(t) = H\}$.

It is easy to see that, for any graph the value of the search game satisfies $v \geq \mu/2$ attained by the hider if he chooses a uniform hiding strategy h_μ . Since any search trajectory S has a unit discovery rate, then for any time $t > 0$, $P(c(S, h_\mu) \geq t) \geq 1 - \frac{t}{\mu}$. Integrating this inequality yields $E(c(S, h_\mu)) \geq \mu/2$.

Fixed Start. A natural way to search a graph is to use a *Chinese postman tour* [9] that is, a closed trajectory that visits all the arcs of Q and has minimal length. Such a tour will be denoted by S^* . Obviously, if Q is Eulerian, then S^* can be chosen as any Eulerian tour (that visits each arc just once). In this case, if $S^*(t)$, $0 \leq t \leq \mu$ is an Eulerian tour, then visiting it with probability $1/2$ in the forward direction (using $S^*(t)$ as the search trajectory) and probability $1/2$ in the backward direction (using $S^*(\mu - t)$ as the search trajectory) is an optimal search strategy because it assures expected capture time at most $\mu/2$. Since the hider can assure at least $\mu/2$ by the uniform hiding strategy, it follows that $v = \mu/2$ for Eulerian graphs. It can also be shown that $v = \mu/2$ holds *only* for Eulerian graphs so, for any non-Eulerian graph $v > \mu/2$. An upper bound for v is μ which is attained *if and only if* Q is a tree.

The search strategy used for Eulerian graphs can be extended to non-Eulerian graphs by using a *random Chinese postman tour* that encircles S^* equiprobably in each direction. It was proven by Gal [10] that a random Chinese postman tour is an optimal search strategy *if and only if* Q is weakly Eulerian (a set of Eulerian subgraphs connected in a tree-like fashion). The optimal

hiding strategy can be constructed by a simple recursive algorithm.

A graph which is not weakly Eulerian is likely to have a very complicated solution. The following misleadingly simple example illustrates the expected difficulties: Assume that Q consists of just three unit arcs b_1 , b_2 , and b_3 connecting two nodes, the origin O and another node A . It is obvious that an optimal search strategy has to pick an arc b_i at random and go from O to A . Surprisingly, upon reaching A , it is *not* optimal to pick another arc at random and fully traverse it (and later the remaining arc). It turns out that the optimal strategy, when reaching A , is to pick an arc, b_j ($j \neq i$) at random and go only a distance x along b_j , where x is chosen by a specific random distribution [7, p. 33] return to A , fully traverse b_k (k different from i and j) and only then complete the traversal of the arc b_j . This strategy was suggested by Donald J. Newman in the late 1970s but the rigorous proof of its optimality is very complicated and took about 15 years to establish [11].

In general, the problem of finding the optimal search strategy is NP-hard as shown by Von Stengel and Werchner [12]. However, they also showed that if the time of search is limited by a (fixed) bound, which is logarithmic in the number of nodes, then the optimal strategy can be found in polynomial time. The search game on a graph can, in general, be formulated as an infinite-dimensional linear program. This formulation with an algorithm for obtaining its (approximate) solution is presented by Anderson and Aramendia [13].

Arbitrary Start. Removing the assumption of a fixed starting point of the searcher, assuming, instead, that the searcher can *choose* the starting point of his trajectory leads to an interesting problem which has been only recently investigated. All the other assumptions, made for the fixed-start games, are the same.

The *Chinese postman path* $\tilde{S}$ is a path, not necessarily closed, which visits all the points of Q and has minimum length. The searcher can use the following strategy which resembles the random Chinese postman tour (used in the fixed-start games).

Simple: Choose the starting point randomly with probability $1/2$ for each end of $\tilde{S}$ and go to the other end along $\tilde{S}$.

Sometimes *Simple* is optimal. For example, if $\tilde{S}$ is an Eulerian path (not necessarily closed) having total length μ , then *Simple* guarantees search time not exceeding $\mu/2$. On the other hand, the hider can guarantee expected search time $\geq \mu/2$ by using a uniform hiding strategy. Thus, the value of this game is $\mu/2$ which implies that *Simple* is optimal. Such an example is the three-arcs graph which is very difficult for the fixed start but very easy for the arbitrary start search game.

Except for the Eulerian path case, described above, *Simple* is optimal for any tree [14], and also for any tree with one or several Eulerian graphs attached [15]. However, Alpern *et al.* [16] have shown that topological characterization of the graphs, for which *Simple* is optimal, is *impossible*. This fact is quite surprising because it contradicts the result for the fixed-start search games.

Searching an Unknown Graph. If the structure of the graph is not known in advance, then the optimal strategy to find the hider is to explore the graph using a randomized version of a well-known search method in computer science called *depth-first search*. This randomized version enables the searcher to find the hider in expected time μ , as shown in Ref. 17, while the usual application of depth-first search can only guarantee 2μ search time.

Search in the Plane

Searching an immobile hider in any two-dimensional convex region (actually a much weaker condition is needed, see Ref. 6, p. 39) with area μ , is similar to searching an Eulerian graph. The searcher has to find a closed curve S^* that covers all the points of the region Q (in the sense that for any $x \in Q$ there exists a $t \geq 0$ such that $d(S^*(t), x) \leq r$). The length of this covering curve can be made less than $(1 + \varepsilon)\mu/2r$, where $\varepsilon \rightarrow 0$ as $r \rightarrow 0$. By encircling this curve equiprobably in each direction the searcher can assure about $\mu/4r$ expected search time. On the other hand, it can easily be shown that the hider can keep

the expected search time above $\mu/4r$ by using a uniform hiding distribution. Thus, $v \sim \mu/4r$ as expected. (The relation $\sim$ means that the ratio between the two terms tends to one as $r \rightarrow 0$.)

MOBILE HIDER

Isaacs' Princess and Monster Game

In his 1965 book [5], Rufus Isaacs presented the following game which he named *princess and monster*. The monster searches for the princess, the time required being the pay-off. They are both in a totally dark room (of any shape) but they are each cognizant of its boundary. Capture means that the distance between the princess and the monster is less than or equal to r the capture radius, which is assumed to be small in comparison with the dimension of the room. The monster, supposed to be highly intelligent, moves at a known speed. We permit the princess full freedom of locomotion.

This game remained an open problem until it was solved by Gal [18], under the condition that the search space Q is convex. Actually a much weaker condition is needed [6, p. 39]. The value, v of the princess and monster game satisfies $v \sim \frac{\mu}{2r}$, where μ is the area of the room (twice the value obtained for an immobile hider). Gal's optimal strategy for the princess is especially interesting: Go to a random location in the room. Stay still for a time interval which is not too short but not too long (the exact formula is given in Ref. 18); go to another, independent, random location; stay still again, and so on. His proposed optimal search strategy is based on the following scheme: Subdivide Q into many *narrow* rectangles. Pick a rectangle at random and search it in a specific way (for details see Refs 6 and 7); after some time pick another rectangle randomly, independently, etc. Note that this type of strategy would not be efficient if the rules of the game were changed in such a way that the hider is informed about the position of the searcher from time to time. A search strategy that is robust to such a change of rules has been presented by Lalley and Robbins [19] as follows: Choose the starting point

uniformly on the boundary of Q . Choose a random direction (from the tangent at that point) θ_1 with density $\frac{1}{2} \sin \theta$, $0 \leq \theta \leq \pi$. Continue with unit speed until you reach the boundary, and choose an i.i.d. direction θ_2 etc. This strategy is robust to partial information: even if the hider is given the position and direction of the searcher from time to time (not too often though) then the hider will not be able to predict its course for very long. It should be noted, though, that Lalley and Robbins' strategy would be ineffective for nonconvex regions but Gal's search strategy is also effective for nonconvex regions and can be adapted to more general problems; for example, a nonconstant capture radius, multidimensional regions, more general cost functions, and search game with several searchers. Several other extensions have been presented by Garnaev (e.g., Ref. 20 in which the probability of detection depends on the distance between the players).

Mobile Hider in a Graph

The princess and monster game on a circle has been suggested by Isaacs [5] as a stepping stone for the game in the region described above. This open problem was (independently) solved by Alpern [21] and Zelikin [22]. (A discrete model has been solved by Wilson [23].) Their optimal search strategy is Alpern's *coin half tour* as follows: Denote the searcher's starting point by O and its antipode by A . Start by tossing a symmetric coin and use the outcome to decide whether to turn left or right as you go (with unit speed) to the antipode; upon reaching A , toss the coin again (independently) and go back to O using the outcome of the toss-up to decide on the direction and so on. This solution was obtained under the assumption that at the beginning of the game, the locations of the searcher and the hider on the circle are uniformly and independently distributed. However, the same search strategy is optimal for a fixed or for an arbitrary starting point. The strategy of the hider is identical to the strategy of the searcher under the assumption of uniformly distributed starting point and also under arbitrary starting point. However, if the searcher starts from a fixed (known)

point, then the hider can take advantage of it by staying at A until time $\mu/2$ (half the circumference) $-\varepsilon$, and starting the coin half tour then.

Except for the circle, solving the princess and monster game on a graph is usually very difficult. For example, even solving the search game on the unit interval (a graph with two nodes and a unit arc connecting them) with an arbitrary start is very difficult. It might be expected that starting at one end (chosen at random) and sweeping as fast as possible the whole interval is an optimal search strategy, but this is not so. The hider's best response to that is to start at distance ε from a random end, and move to the other end with unit speed. This leads to $0.75 (-\varepsilon)$ expected search time but the searcher can do better and the value of the game is about 0.7. This unexpected behavior, and an approximate solution of the game on the interval has been presented by Alpern *et al.* [24].

SEARCH IN UNBOUNDED DOMAINS

Linear Search Problem

The *linear search problem* was introduced by Bellman [25] and, independently, by Beck [26] as follows: A target is located on the real line, at a point H , with a known probability distribution. A searcher, whose maximal velocity is 1, starts from the origin O and wishes to discover the target in minimal expected time. Usually, it is assumed that changing the direction of motion can be done instantaneously.

Much research has been carried out by Beck and others [27,28] but the linear search problem for a general probability distribution is still unsolved. However, a dynamic programming algorithm can produce a solution for any discrete distribution [29], and also an approximate solution, with any desired accuracy, for any probability distribution [7].

The seminal paper by Beck and Newman [30] considers the linear search problem within the framework of a search game. In order to have a meaningful game, they allow only hiding strategies with expected distance (from O) at most λ . The constant λ is assumed to be known to the searcher

but it turns out that the optimal search strategies do not depend on λ . Within this framework they show that the minimax search trajectory is to oscillate around O , *doubling* the amplitude at each step. The doubling trajectory guarantees capture by time $9|H|$ so that the expected capture time is at most 9λ and this constant is the best that can be achieved by a fixed trajectory.

They also show that the game has a value equal to $(1 + \bar{g})\lambda$ ($\doteq 4.6\lambda$) where $\bar{g}$ minimizes $\frac{g+1}{\ln g}$. An optimal (mixed) search strategy that achieves this value uses a geometric trajectory, with the generator $\bar{g}$, multiplied by a random constant $c_u = \bar{g}^u$, where u is chosen at random by the uniform distribution in the interval $[0, 2)$. Thus, the n th step size of the search strategy is $c_u \bar{g}^n$.

Rather than restricting the hider, the approach used by Gal [31] is to normalize the cost function by the distance of the target from the origin. The two approaches lead to equivalent results [6]. This type of normalization was new at that time but is now called the *competitive ratio* in computer science literature and is a standard tool in analyzing online algorithms [32].

The online solution with a positive turn cost d , is given by Demaine *et al.* [33]. The presented trajectory guarantees paying at most $9|H| + 2d$, having the (minimal) competitive ratio 9 with respect to $|H|$ plus the minimum corresponding additive term. The corresponding step size is $d(2^n - 1)/2$ for the n th step, $n = 1, 2, \dots$. It also turns out that optimal randomized strategies for searching the line in the presence of turn cost have the same (minimal) competitive ratio of about 4.6, as in the model without turn cost.

Finding Minimax Search Trajectories

Search games in unbounded domains often use a minimax solution for a homogenous unimodal functional with two arguments representing a search trajectory and a hiding point. It was shown by Gal and Chazan [34] that a minimax search trajectory for such a functional is always a geometric sequence (or exponential functions for continuous problems). This result has been developed in Ref.

6 as a general tool. In order to find the minimax trajectory all that needed is to minimize a simple function over a single parameter (the generator of this sequence) instead of searching over the whole trajectory space. This tool has been used for the linear search problem and also in the problems, to be discussed, of searching a set of rays (star search) and searching in the plane using exponential spirals. It has also been used for minimax search on the boundary of a region consisting of two rays in the plane. That problem has been presented by Baeza-Yates [35], and solved by Gal using the general tool [7, pp. 154–157].

Geometric trajectories are useful in other fields too in order to obtain effective algorithms, as shown by Chrobak and Kenyon-Mathieu [36]. That survey describes the “doubling” method for designing online and offline approximation algorithms. The rough idea is to use geometrically increasing estimates on the optimal solution to produce fragments of the algorithm’s solution. This method is illustrated by discussing several applications where doubling is used. These areas, in addition to searching, include bidding, minimum latency tours, scheduling, and clustering. This work raises the hope that doubling will become a standard tool for designing approximation algorithms.

Star Search

The natural extension of the linear search problem to $M > 2$ unbounded rays radiating from the origin, has been presented and solved by Gal [37]. It was later rediscovered in computer science literature [35] and has been called the *cow path search* in Ref. 38 which also presented several applications.

Gal showed that the optimal trajectory is *periodic* (visiting each ray every M th time) with *monotone*-increasing step size and, using the general tool described in the section titled “Finding Minimax Search Trajectories,” demonstrated that the minimax trajectory has a geometric step size with generator $\frac{M}{M-1}$. The minimax trajectory achieves the competitive ratio $1 + 2 \frac{M^M}{(M-1)^{M-1}} \sim 2eM$ ($\doteq 5.4M$) for large M .

Similar to the linear search problem, the (expected) competitive ratio can be improved

by using mixed search strategies. Specifically, the geometric trajectory with the generator $\bar{g}$, that minimizes $\frac{2(\bar{g}^M - 1)}{M(\bar{g} - 1) \ln \bar{g}}$ multiplied by a random constant $c_u = \bar{g}^u$ where u is uniformly distributed in the interval $[0, M)$, is optimal: using a periodic trajectory with step size $c_u \bar{g}^u$, leads to competitive ratio of about $3.09M$. In contrast to the pure strategy case, however, the optimality proof applies only to strategies that use periodic and monotone trajectories [6, 39–41].

López-Ortiz and Schuierer have solved several extensions of the star search. If a bound, D , is given for the distance of the hiding point from the origin then they showed that the competitive ratio is $1 + 2 \frac{M^M}{(M-1)^{M-1}} - O(1/\log D)$. A nice feature of the presented trajectory is that it is not necessary to know an upper bound on D in advance. A similar phenomenon occurs in the Beck and Newman strategies that are independent on the bound for the expected hiding distance λ .

Online star search by several agents who move in parallel has been solved in Ref. 43. If there are p searchers, then the competitive ratio is $1 + 2 \left(\frac{M}{p} - 1 \right) \left(\frac{M}{M-p} \right)^{M/p}$.

Searching in the Plane

Optimal Sweeping. The continuous version of the general tool described in the section titled “Finding Minimax Search Trajectories” is useful to find the minimax search trajectory for the following search problem in the plane. An (immobile) hider is located at a point in the plane with unknown distance and direction from the origin O . The searcher chooses a trajectory, starting from O and discovers the hider at the moment when the hider is covered by the area swept by the radius vector $\mathbf{R}$ of his trajectory. Natural search trajectories have the following *periodic and monotonic* property: the angle θ of the radius vector is always strictly increasing, and the trajectory does not intersect itself. Under this assumption, it can be proven that a minimax search trajectory can be found in the family of exponential spirals, that is, $|\mathbf{R}| = e^{b\theta}$, where $b > 0$ is a constant. The competitive ratio is $e^{2\pi b} \sqrt{1 + 1/b^2}$ with minimal value of about 17.3, attained

at $b \doteq 0.16$. It was shown by Gal [6] that this strategy is the best among all monotone and periodic strategies. Since then, it has been an open problem whether the given strategy is optimal in general. A recent work of Langetepe [44] has settled this old open problem and showed that the spiral search described above is indeed the globally optimal trajectory.

“Swimming-in-a-Fog” Problem. The following problem has been proposed by Bellman [45]. A person has been shipwrecked in a fog (at the point O) and wishes to minimize the maximum time required to reach the shore. The shape of the shore is known (say a straight line) and some information is given about its distance from O .

If the distance, D , to the shore is known exactly, then the minimax trajectory is given by Isbell [46] as follows: For convenience assume that $D = 1$. Imagine a clock face around O ; walk towards 1 o'clock for $\sqrt{4/3}$ units; then, turn on the tangent that strikes the unit circle at 2 o'clock; follow the circle to 9 o'clock and, finally, continue on a tangent for one more unit (until reaching the tangent to the unit circle at 12 o'clock). The length of this minimax trajectory is $(7\pi/6 + \sqrt{3} + 1)D \doteq 6.4D$. However, this trajectory is not effective unless D is known exactly.

An online framework for the general problem is presented in Ref. 6. The goal is to minimize the ratio between the distance traveled until reaching the shore and the unknown distance to the shore, D . It has been suggested that the solution could be an exponential spiral but the problem seems difficult and is still open.

SELECTIVE SUPPORT VECTOR MACHINES

ONUR SEREF

Technology, Virginia Polytechnic
Institute and State University,
Blacksburg, Virginia

Support vector machines (SVMs) are among the increasingly popular and widely used supervised machine learning methods [1]. SVMs are generally used to classify pattern vectors which are assumed to belong to two linearly separable sets of positive and negative labeled pattern vectors. The classification function is defined by a hyperplane that separates these two classes. SVM classifier finds the hyperplane that maximizes the distance between the two convex hulls formed by the pattern vectors in each class. SVM can be extended to classification of nonlinear data by implicitly embedding the original data in a nonlinear space using kernel functions [2]. SVM training is based on optimizing a quadratic convex function that is subject to linear constraints, which is a well-known problem with many efficient solutions [3]. Due to the strong statistical learning background and efficient implementations, SVM methods have found a wide spectrum of application areas recently, ranging from pattern recognition [4] and text categorization [5] to biomedicine [6–8] and financial applications [9,10].

A generalization of SVM classification is selective classification [11]. In selective classification, n sets of positive and negative labeled pattern vectors with t pattern vectors in each set are given. All pattern vectors in a set share the same label. The objective is to select a single pattern vector from each of the n sets such that the selected positive and negative pattern vectors produce the best possible solution for a binary classification problem. In the SVM context, this classification problem is the quadratic optimization problem that maximizes the margin between

positive and negative pattern vectors. The standard SVM problem can be considered as a special case of selective classification, where $t = 1$.

Selective classification is similar to the multiple-instance classification problem [12] with regard to its input. However there is a significant difference in the classification scheme. In selective classification, the selection process is symmetrical with respect to the positive and negative sets of pattern vectors with the objective of selecting a single pattern vector from each set. In multiple-instance classification, the objective is to classify positive and negative sets by classifying all pattern vectors in each set. According to the asymmetrical classification scheme in multiple-instance classification, a set is classified as positive if one or more pattern vectors in it are classified as positive whereas a set is classified negative only if all of the pattern vectors in it are classified as negative.

Selective classification poses a hard combinatorial optimization problem. It is shown that the SVM formulation for selective classification is NP-hard [13]. An alternative approach is developed based on a restricted amount of free slack that decreases the influence of misclassified pattern vectors on the separating hyperplane. The optimization problem in this approach is also a convex quadratic optimization problem with linear constraints, and can be kernelized for nonlinear classification problems. The solution to this problem has nice properties that allow simple and efficient algorithms to be developed. In one possible algorithm, the pattern with a small margin can be identified by providing a small amount of restricted free (unpenalized) slack, and such pattern vectors can be iteratively eliminated until one pattern vector remains in each set. In another algorithm, one can provide a larger amount of restricted free slack to identify and eliminate all but one pattern vector from each set in a single step, which would be equivalent to directly selecting the final pattern vector with a large margin in

each set. Both algorithms produce successful results in simulated data as well as real-life neural data from a visuomotor categorical discrimination task.

Selective SVM requires a basic understanding of the standard SVM formulation. The concepts to develop kernelized formulations for selective SVM through Lagrangian duality are similar to those involved in the standard SVM literature. Therefore, it is appropriate to start with a short review of SVMs in the next section.

SUPPORT VECTOR MACHINES

Let $\mathbf{X}$ be a set of pattern vectors $\mathbf{x}_i \in \mathbb{R}^d$ with class labels $y_i \in \{1, -1\}$ which either belong to the positive or negative labeled sets of pattern vectors. The problem of classifying these pattern vectors is equivalent to finding a function $f(\cdot)$ which correctly assigns a class label for a given pattern vector $\mathbf{x}$. A hyperplane separates positive and negative pattern vectors, and it is represented as $(\mathbf{w}, b)$, where $\mathbf{w}$ is the normal vector to the hyperplane and b is the bias. The distance γ between the hyperplane and the closest pattern vectors (support vectors) is called the *margin of the separating hyperplane*. This hyperplane is represented by the support vectors, which give the classifier its name, SVM. The hyperplane with the maximum margin is called the *maximum margin hyperplane*. Note that there is an inherent degree of freedom to represent the same hyperplane by multiplying $\mathbf{w}$ and b with $\lambda > 0$. Depending on the value of λ , the distance between $\mathbf{x}$ and the hyperplane changes. Assuming that this value is greater than a constant value, such as a unit distance of one, it is easy to show that the geometric margin becomes $1/\|\mathbf{w}\|$ [14]. The pattern vectors in the positive and negative classes may not be separable. In this case, introducing slack variables ξ_i for misclassified pattern vectors and penalizing them by $C/2$ for a chosen value of $C > 0$ leads to the following formulation:

$$\min_{\mathbf{w}, b, \xi} \frac{1}{2} \|\mathbf{w}\|^2 + \frac{C}{2} \sum_{i=1}^n \xi_i^2, \quad (1a)$$

$$\begin{aligned} \text{subject to: } & y_i(\langle \mathbf{w} \cdot \mathbf{x}_i \rangle + b) \geq 1 - \xi_i \\ & i = 1, \dots, n. \end{aligned} \quad (1b)$$

Although the formulation (1) finds a linear separating hyperplane, its *Lagrangian dual* can be modified to use nonlinear maps to embed the pattern vectors in a higher dimensional space in such a way that a hyperplane can separate the mapped pattern vectors in the embedded space. This embedding is done via the *kernel trick*. The mapping is defined over dot product *Hilbert spaces*. The Lagrangian dual of the soft margin classification problem provides a formulation, in which dot products can be introduced. The dot product can be replaced with kernels to introduce nonlinear mapping. The Lagrangian dual of formulation 1 is given as follows:

$$\begin{aligned} \max_{\alpha} \quad & \sum_{i=1}^n \alpha_i - \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n y_i y_j \alpha_i \alpha_j \langle \mathbf{x}_i \cdot \mathbf{x}_j \rangle \\ & - \frac{1}{2C} \sum_{i=1}^n \alpha_i^2 \end{aligned} \quad (2a)$$

$$\text{subject to: } \sum_{i=1}^n y_i \alpha_i = 0, \quad (2b)$$

$$\alpha_i \geq 0, i = 1, \dots, n. \quad (2c)$$

The classification function can be written as $f(\mathbf{x}) = \text{sign}(\langle \mathbf{w} \cdot \mathbf{x} \rangle + b)$ for a pattern vector $\mathbf{x}$ with unknown class label. From complementary slackness, the bias b can be calculated using a pattern vector $\mathbf{x}_i$ which is also a support vector, that is $\alpha_i > 0$ as $b = y_i(1 - \alpha_i) - \sum_{i=1}^n y_i \alpha_i \langle \mathbf{w} \cdot \mathbf{x}_i \rangle$. One can use the equivalence $\mathbf{w} = \sum_{i=1}^n \sum_{k=1}^t y_i \alpha_i \mathbf{x}_i$ to calculate $\mathbf{w}$ from the solution to Equation (2).

The convenience of the dual formulation in Equation (2) is that it has only one constraint, and the dot products allow nonlinear kernels $K(\mathbf{x}_i, \mathbf{x}_j)$ to be incorporated in the formulation by replacing the dot product $\langle \mathbf{x}_i \cdot \mathbf{x}_j \rangle$. For example, the Gaussian kernel is among the most commonly used kernels, and is given as follows:

$$K(\mathbf{x}_i, \mathbf{x}_j) = \left\{ \frac{\|\mathbf{x}_i - \mathbf{x}_j\|^2}{\sigma} \right\}. \quad (3)$$

SELECTIVE SUPPORT VECTOR MACHINE FORMULATIONS

Selective SVM is a generalization of the standard SVM in which sets of pattern vectors replace individual pattern vectors. The main objective is to select a single pattern vector from each set such that the margin is maximized between the selected positive and negative pattern vectors. However this problem is highly combinatorial and finding the optimal solution is very hard even for small problems. Alternative efficient formulations such as a convex quadratic formulation that features a restricted amount of free slack can find good solutions.

Combinatorial Formulation

Consider that each pattern vector in a standard SVM problem is replaced with a set of pattern vectors sharing the same class label. Then, the selective margin maximization problem can be defined as follows: Let $\mathbf{X} = \{\mathbf{X}_1, \dots, \mathbf{X}_n\}$ be sets of pattern vectors with t pattern vectors $\mathbf{x}_{i,1}, \dots, \mathbf{x}_{i,t}$ in each set $\mathbf{X}_i$. Let $y = \{y_1, \dots, y_n\}$ be the corresponding labels for each set $\mathbf{X}_i$ with each pattern vector $\mathbf{x}_{i,k}$ sharing the same label y_i . Select exactly one pattern vector $\mathbf{x}_{i,k}$ from each set $\mathbf{X}_i$ such that the margin between the selected positive and negative pattern vectors is maximized. This problem can be formulated as a quadratic mixed 0–1 programming problem as follows:

$$\min_{\mathbf{w}, b, \xi, v} \frac{1}{2} \|\mathbf{w}\|^2 + \frac{C}{2} \sum_{i=1}^n \sum_{k=1}^t \xi_{i,k}^2, \quad (4a)$$

subject to:

$$y_i(\langle \mathbf{w} \cdot \mathbf{x}_{i,k} \rangle + b) \geq 1 - \xi_{i,k} - M(1 - v_{i,k}), \quad (4b)$$

$$i = 1, \dots, n; k = 1, \dots, t;$$

$$\sum_{k=1}^t v_{i,k} = 1 \quad i = 1, \dots, n; \quad (4c)$$

$$v_{i,k} \in \{0, 1\} \quad i = 1, \dots, n; k = 1, \dots, t. \quad (4d)$$

Note that this formulation is similar to Equation (1), except for the extra term $M(1 - v_{i,k})$ in Equation (4b) and the new constraints (4c and 4d). M is a sufficiently

large positive number. Binary variables $v_{i,k}$ indicate whether the k th pattern vector from set i is selected or not. Note that when $v_{i,k} = 0$, the right side of Equation (4b) becomes sufficiently small such that the constraint is always satisfied, which is equivalent to removing that pattern vector. The constraint in Equation (4c) ensures that only one pattern vector is included from each set. It is clear that for sufficiently high penalty C , the selective SVM formulation can be considered as a *hard-selection* problem without the slack variables $\xi_{i,k}$, whose solution would provide a hyperplane that can completely separate the selected positive and negative pattern vectors.

Now, consider the following decision version of the problem. Let $\mathbf{X}_i$ denote a set of d -dimensional t pattern vectors. Assume that there are n such sets and all vectors $\mathbf{x}_{i,k}$ in each set $\mathbf{X}_i$ are labeled with the same label $y_i \in \{1, -1\}$. Let v^* denote a selection, where a single pattern vector $\mathbf{x}_{i,k^*}$ is selected from each set $\mathbf{X}_i$. Is there a selection v^* , in which all positive and negative pattern vectors can be separated by a hyperplane? This decision problem is shown to be NP-complete [13]. The reduction for the NP-completeness proof is from the PARTITION problem [15]. This result implies that the original combinatorial formulation (4) for the selective SVM formulation is NP-hard.

Alternative Formulation with Restricted Free Slack

The combinatorial problem is intractable even for small to medium-sized problems. An alternative convex quadratic formulation can be considered, in which a restricted amount of unpenalized slack is provided. Free slack gives the separating hyperplane some flexibility to adjust itself in order to diminish the influence of those pattern vectors with small or negative (misclassified) distance from the hyperplane. Given this flexibility, the hyperplane realigns itself with respect to the further pattern vectors with larger margin.

Consider a total, restricted, free slack amount of Υ , which is available for all pattern vectors. Note that a very small amount of free slack would make a very small difference compared to the hyperplane

obtained by the standard SVM formulation, whereas a very large free slack amount would yield trivial solutions. Depending on the selection scheme, the amount of total free slack may vary. The corresponding formulation is given as follows:

$$\min_{\mathbf{w}, b, \xi, v} \frac{1}{2} \|\mathbf{w}\|^2 + \frac{c}{2} \sum_{i=1}^n \sum_{k=1}^n \xi_{i,k}^2, \quad (5a)$$

subject to:

$$y_i(\langle \mathbf{w} \cdot \mathbf{x}_i \rangle + b) \geq 1 - \xi_{i,k} - v_{i,k} \\ i = 1, \dots, n; k = 1, \dots, t; \quad (5b)$$

$$\sum_{i=1}^n \sum_{k=1}^n v_{i,k} \leq \Upsilon; \quad (5c)$$

$$v_{i,k} \geq 0 \quad i = 1, \dots, n; k = 1, \dots, t. \quad (5d)$$

Note that this formulation is similar to the standard SVM formulation with a convex quadratic objective function and linear constraints. The Lagrangian dual of this formulation can also be derived for nonlinear classification. The dual formulation is given as follows:

$$\max_{\alpha, \beta} \sum_{i=1}^n \sum_{k=1}^t \alpha_{i,k} - \frac{1}{2} \sum_{i=1}^n \sum_{k=1}^t \sum_{j=1}^n \\ \times \sum_{l=1}^t y_i y_j \alpha_{i,k} \alpha_{j,l} \langle \mathbf{x}_{i,k} \cdot \mathbf{x}_{j,l} \rangle \\ - \frac{1}{2C} \sum_{i=1}^n \sum_{k=1}^t \alpha_{i,k}^2 - \Upsilon \beta \quad (6a)$$

subject to:

$$\sum_{i=1}^n \sum_{k=1}^t y_i \alpha_{i,k} = 0 \quad (6b)$$

$$0 \leq \alpha_i \leq \beta \quad i = 1, \dots, n; k = 1, \dots, t. \quad (6c)$$

The bias is equal to $b = y_i(1 - \alpha_{i,k}/C) - \langle \mathbf{w} \cdot \mathbf{x}_{i,k} \rangle$, if there exist $v_{i,k} = 0$ for some i and k . Otherwise, $\alpha_{i,k} = \beta$ for all $i = 1, \dots, n$ and $k = 1, \dots, t$, in which case the bias becomes $b = (\sum_{(i,k) \in A} y_i)(|A|(1 - \beta/C) - V - \sum_{(i,k) \in A} \langle \mathbf{w} \cdot \mathbf{x}_{i,k} \rangle)$, where $A = \{(i, k): \alpha_{i,k} > 0\}$. As in the standard SVM formulation, one can use the equivalence $\mathbf{w} = \sum_{i=1}^n \sum_{k=1}^t y_i \alpha_{i,k} \mathbf{x}_{i,k}$

to calculate $\mathbf{w}$ from the solution to Equation (6). For the nonlinear cases, linear dot products $(\mathbf{x}_{i,k} \cdot \mathbf{x}_{j,k})$ in Equation (6) can be replaced with an appropriate kernel $K(\mathbf{x}_{i,k}, \mathbf{x}_{j,k})$.

Free slack acquired by each pattern vector is either 0 or linearly proportional to its distance from the optimal hyperplane depending on the total slack provided. This result derives from the properties one can observe about the solutions to formulations (5 and 6). The first property is that constraint (5c) is always binding. In other words, total amount of free slack Υ is always consumed, which can be shown using complementary slackness. The next property is that if the penalized slack or the free slack is positive, that is $\xi_{i,k} + v_{i,k} > 0$, then the corresponding constraint (5b) is binding, which can be inferred from the optimality conditions. Using these properties, the following relationship between the penalized and free slack can be shown. Let $\xi_{\max} = \max_{i,k} \{\xi_{i,k}\}$, then $v_{i,k} = 0$ if $\xi_{i,k} < \xi_{\max}$ and $v_{i,k} > 0$ if $\xi_{i,k} = \xi_{\max}$.

This main result basically states that all pattern vectors with a functional margin of $d_{i,k} = y_i(\langle \mathbf{w} \cdot \mathbf{x}_{i,k} \rangle + b) < 1$ incur a penalty of $\xi_{i,k} = \min(1 - d_{i,k}, \xi_{\max})$. Free slack for pattern vectors with $\xi_{i,k} = \xi_{\max}$ is equal to $v_{i,k} = 1 - \xi_{\max} - d_{i,k}$, whose sum is equal to Υ . In other words, without loss of generality, the free slack acquired by a positive labeled pattern vector is linearly proportional to its distance from the hyperplane $\langle \mathbf{w} \cdot \mathbf{x}_{i,k} \rangle + b = 1 - \xi_{\max}$. Examples of such pattern vectors are shown in Fig. 1. Further details can be found in Ref. 13. This interpretation leads to a few possible methods to maximize the margin between the selected points.

SELECTION METHODS

The solution to the alternative formulation allows pattern vectors that are close to the hyperplane to use free slack and provide more flexibility for the separating hyperplane. The selection is done with respect to the orientation of the hyperplane. Compared to the hard combinatorial formulation with an exact solution, the alternative formulation can be referred to as *soft selection*. The two methods introduced in this section are based on the

Figure 1. Example showing the relationship between penalized slack and free slack.

soft-selection formulation. The first method uses a small amount of restricted free slack for the soft-selection formulation and iteratively eliminates a single pattern vector with small or negative distance from the hyperplane from each set. The second method provides a larger amount of free slack to diminish the influence of multiple pattern vectors from each set and solves the soft-selection formulation only once to identify the pattern vector with the maximum distance within each set.

Iterative Elimination

The soft-selection formulation is mainly developed to give the separating hyperplane more flexibility and, at the same time, to

identify those pattern vectors which are misclassified or very close to the hyperplane. Such pattern vectors require more free slack among the pattern vectors within their set. One can obtain a more separated subset of positive and negative pattern vectors if such pattern vectors are removed. An intuitive basic approach is as follows: at each iteration, supply an incremental amount of free slack of n (1 unit per set), solve the soft-selection problem, identify the pattern vector with the minimum distance for each set and remove it, and repeat the iterations with the updated set of pattern vectors until only one pattern vector per set remains. This approach is summarized in Algorithm 1.

Algorithm 1. Iterative Elimination.

```

1:  $\mathbf{X} \leftarrow \mathbf{X}(0)$ 
2:  $t \leftarrow t(0)$ 
3: while  $t > 1$  do
4:    $\{\mathbf{w}, b\} \leftarrow \text{SOFT SELECTION}(\mathbf{X}, \mathbf{y}, n)$ 
5:    $r \leftarrow \emptyset$ 
6:   for  $i = 1$  to  $n$  do
7:      $k^* = \arg \min_{k=1, \dots, t} \{y_i (\langle \mathbf{w} \cdot \mathbf{x}_{i,k} \rangle + b)\}$ 
8:      $r = r \cup \mathbf{x}_{i,k^*}$ 
9:   end for

```

```

10:  $\mathbf{X} \leftarrow \mathbf{X} \setminus r$ 
11:  $t \leftarrow t - 1$ 
12: end while
13: return  $\mathbf{X}$ 

```

In Algorithm 1, $\mathbf{X}(0)$ is the original input of pattern vectors, $\mathbf{y}$ is the vector of labels for each set $\mathbf{X}_i$, n is the total free slack amount provided for the soft-selection problem, $(\mathbf{w}, b)$ is the separating hyperplane, $y_i(\langle \mathbf{w} \cdot \mathbf{x}_{i,k} \rangle + b)$ is the distance of $\mathbf{x}_{i,k}$ from the hyperplane, which can be negative if $\mathbf{x}_{i,k}$ is misclassified, $t(0)$ is the initial number of pattern vectors in each set, and r is the set of pattern vectors to be removed at each iteration.

Note that when total free slack is zero, the soft-selection problem reduces to a standard SVM problem. A naïve method can be considered, in which the total free slack is given as zero which reduces the soft-selection formulation to a standard SVM formulation. This naïve method can set a basis to compare the performance of the soft-selection formulation to the standard SVM formulation.

Direct Selection

The alternative to the iterative elimination method is to provide enough free slack to eliminate $t - 1$ pattern vectors in a single iteration. From another perspective, the extra free slack would diminish the influence of these $t - 1$ pattern vectors and let the separating hyperplane align itself with respect to the furthest pattern vectors within each set. Such pattern vectors can directly be selected after solving the soft-selection problem only once. For this algorithm, a total amount of $n(t - 1)$ free slack is provided. Direct selection is summarized in Algorithm 2 using a notation similar to Algorithm 1.

Algorithm 2. Direct Selection.

```

1:  $\{\mathbf{w}, b\} \leftarrow \text{SOFT\_SELECTION}(\mathbf{X}(0), \mathbf{y}, n(t - 1))$ 
2:  $\mathbf{X} \leftarrow \emptyset$ 
3: for  $i = 1$  to  $n$  do
4:    $k^* = \arg \max_{k=1, \dots, t} \{y_i(\langle \mathbf{w} \cdot \mathbf{x}_{i,k} \rangle + b)\}$ 
5:    $\mathbf{X} = \mathbf{X} \cup \mathbf{x}_{i,k^*}$ 
6: end for
7: return  $\mathbf{X}$ 

```

COMPUTATIONAL RESULTS

Soft-selection formulation and the two algorithms developed can be applied to simulated data as well as real-life data. The main basis of comparison for the simulated data is the naïve method for selection. The computational results included are provided to demonstrate the performance of the algorithms developed. The results regarding the first data set involve simulated data, in which the input pattern vectors are distributed uniformly in hyperspheres with respect to a number of parameters at varying levels. The second data set involves real-life data, in which electrical recordings from a macaque monkey brain are arranged as input for a selective classification task and the results are compared to those obtained with standard SVM classifiers.

Simulated Data and Performance Measure

The simulated data is generated using two parameters that determine the *dimensionality* and the *separability* of the pattern vectors. Let $S_k, k = 1, \dots, n$ denote the set of pattern vectors formed by including the k th pattern vector from each set $\mathbf{X}_i$. For each S_k, n random pattern vectors are generated, which are uniformly distributed in a hypersphere with radius r . The center of each hypersphere is also distributed uniformly in a hypersphere with radius c . Parameter r is kept constant so that c determines the separability of the data, which is the first parameter to be varied. The dimension of the data, denoted by d , is the second parameter.

The performance measure is the objective function value obtained by the standard SVM formulation for the final set of selected pattern vectors. For this purpose, the restricted total free slack can be set to zero, in which case the standard SVM formulation is obtained. The results are later normalized for each combination of dimension d and separability c with all of the results

obtained from the compared methods. The normalization is done by measuring the mean $\mu_{d,c}$ and the standard deviation $\sigma_{d,c}$ of the objective function values obtained from all of the compared methods, and normalizing each objective function value using $\mu_{d,c}$ and $\sigma_{d,c}$.

Iterative Elimination versus Naïve Elimination

Simulated data is generated for $d = 2, 4, \dots, 20$ and $c = 0, r/2, r$. Number of pattern vectors per set t is set to 6 and $p = 1$ unit of free slack per set is provided. For each combination of the parameters, 100 instances of simulated data sets are generated and tested using iterative elimination and naïve elimination, and the results are normalized. Let z_I and z_N denote the average normalized objective function values obtained from iterative elimination and naïve elimination. In Fig. 2, $z_N - z_I$ values for $d = 2, 4, \dots, 20$ are plotted for each c value. It is clear from the figure that as the dimensionality increases, the iterative elimination is significantly superior to the naïve elimination method. The difference becomes more apparent for higher levels of data separation. This result clearly shows

the success of iterative elimination due to the flexibility of the separating hyperplane incorporated by the restricted free slack.

Direct Selection

Simulated data is generated for $d = 2, 4, \dots, 20$ and $c = 0, r/2, r$. Number of pattern vectors per set t is set to 6 and $p = 1, \dots, 5$ units of free slack per set is provided. In Fig. 3, the effect of the increase in total slack is shown. The three graphs in the figure are in the order of increasing separation in the data. In each graph, the objective function values for the highest total slack parameter $p = 5$ is assumed to be the base value and the differences between the others and the base, $z_i - z_5, i = 1, \dots, 4$ are graphed. The amount of free slack does not contribute significantly for completely overlapping data in the graph 3a. However, it is clear from graph 3b that when there is some separability in the data, increasing amount of slack improves the performance of the method for higher dimensions. This difference is even more amplified in graph 3c for higher separability values. In graphs 3b and 3c, the increase in the difference between $p = 5$ and the others

Figure 2. Normalized difference between iterative elimination and naïve elimination methods.

Figure 3. Effect of the amount of free slack on data with separability: (a) $c = 0$, (b) $c = r/2$, (c), $c = r$.

Figure 4. Comparison of iterative elimination and direct selection methods.

for higher dimensional data are also apparent. These results imply that the free slack parameter can be set as $t - 1$ (per set) for a data set with t pattern vectors in each set.

Comparison of the iterative elimination and direct selection completes the computational results on simulated data. The separability and dimensionality parameters are set in the same way as the previous computational results. Free slack parameter for direct selection is $p = t - 1$, where $t = 6$ again. In Fig. 4, the performances of iterative elimination and direct selection are shown with the values $z_D - z_I$, where z_D and z_I are normalized objective function values obtained from iterative elimination and direct selection methods, respectively. The results fluctuate and there is no significant

dominance of one method over the other. However, it can be observe from the figure that, on the average, the iterative elimination method performs slightly better than the direct elimination method.

A Real-Life Application

As an example of a real-life application, iterative elimination method is applied to a neuroscience problem. The data consists of local field potentials (LFPs) collected from multiple channels implanted in different cortical areas of a macaque monkey during a visual discrimination task. This task involves recognizing a visual “go” stimulus which is followed by a motor response. The visuomotor task is repeated multiple

times in different sessions for the same experiment with different stimuli–response combinations. Each repetition of the task is called a *trial*. The data can be arranged with respect to different stages of this task. The main objective is to be able to detect the differences between the different states of the macaque brain over the time course of the task by classifying the multidimensional and highly nonlinear neural data.

The visual stimuli are designed to create *lines* and *diamonds*. The “go” stimuli are chosen to be either lines or diamonds from one session to another. Three different stages are anticipated: (i) the detection of the visual stimulus, (ii) the categorical discrimination of the stimulus, and (iii) the motor response. The first and the third stages are relatively easy to detect; however, the second stage has not been detected in previous studies [16]. This stage involves a complex cognitive process whose onset and length vary over time.

Classification is performed with the pattern vectors collected at a specific time T^* from each trial. The classification accuracy obtained from each time point shows the time intervals when the two observed states of the monkey brain are different. However, there are temporal variations in each trial regarding the timing of the observed stages. The motivation behind the development of selective classification methods is to perform classification while accounting for these temporal variations in the underlying complex

cognitive processes. The standard SVM classifier is hindered by the noisy recordings due to these temporal variations. Given an appropriate time window, it can be assumed that one of the recordings within this window from each trial comes from the same underlying process to be detected. Selecting the most distinguishable recording from each trial at a given time window centered around T^* is a hard problem. Therefore one can use iterative elimination to detect and remove noisy recordings iteratively, to achieve better recordings for the given time window.

Nonlinear iterative elimination method is applied with a window of three recordings from each trial for each time point. This window corresponds to 15 ms. The recordings with the minimum distance are eliminated from each set, at each iteration. This procedure is repeated until only one pattern vector remains from each trial within the time window. The classification accuracy of the selected recordings from each time window is evaluated with the standard SVM classifier using 10-fold classification. In Fig. 5, the comparison of the classification accuracy results from iterative elimination, and the results from the standard SVM classification are given. The iterative elimination shows a consistent increase around 10%. This increase can be adjusted by the *baseline* approach. In order to create a baseline, class labels are randomly assigned to pattern vectors and iterative elimination is applied in order to

Figure 5. Comparative classification accuracy results: (a) standard SVM, baseline, and after applying selective SVM; (b) difference between the baseline and selective SVM results.

find the increase in the accuracy for random data and subtract it from the original accuracy results. The baseline is shown in Fig. 5a and the difference between the original accuracy results and the baseline results are given in Fig 5b. The peak around 160 ms in this graph is very clear. This result matches the anticipated interval of the categorical discrimination stage.

CONCLUSION

Selective SVMs are generalizations of the standard SVM classifiers. Sets of pattern vectors sharing the same label are given as input. One pattern vector is selected from each set in order to maximize the classification margin with respect to the selected positive and negative pattern vectors. The problem of selecting the best pattern vectors is referred to as the *hard-selection problem*, which is NP-hard. Soft-selection formulation is a tractable alternative which can be applied to linear and nonlinear data. Selectivity in the soft selection is controlled by the restricted free slack concept. The intuition behind this concept is to reverse the combinatorial selection problem by detecting influential pattern vectors which require free slack in order to decrease their influence on the separating hyperplane. One can find a selection with a large margin by iteratively removing such pattern vectors. The iterative elimination method is developed based on this scheme. Another alternative approach is to provide enough free slack to identify all $t - 1$ out of t pattern vectors to be removed at once, which leads to the direct selection method. Iterative elimination method using restricted free slack produces results superior to the case when no free slack is provided, in which case the classification is done using a standard SVM formulation. Iterative elimination and the direct selection methods produce comparable results.

The motivation for the development of selective classification methods comes from the classification of cognitive states in a visuomotor pattern discrimination task. Due to the temporal noise in the data, the classification results obtained are poor

with standard SVM methods. Sliding small time-windows of recordings from trials are considered as sets of pattern. Well-separated recordings are selected by the iterative elimination method. The selected recordings are evaluated with standard SVM methods, which result in a significant increase in the classification accuracy over the entire timeline of the task. The increase is adjusted by a baseline method which isolates the actual improvement peaks. These peaks clearly mark the categorical discrimination stage of the visuomotor task, which involves a complex cognitive process that has not been detected by previous studies. This result suggests that the proposed selective classification methods are capable of providing promising solutions for other classification problems in neuroscience.

SELF-DUAL EMBEDDING TECHNIQUE FOR LINEAR OPTIMIZATION

KEES ROOS

Faculty of Electrical Engineering,
Mathematics and Computer Science,
Delft University of Technology, Delft,
The Netherlands

As in the article titled **Central Path and Barrier Algorithms for Linear Optimization** in this encyclopedia, we consider the linear optimization (LO) problem in the standard form

$$\min \{c^T x : Ax = b, x \geq 0\}, \quad (\text{P})$$

with its dual problem

$$\max \{b^T y : A^T y + s = c, s \geq 0\}. \quad (\text{D})$$

Here, $A \in \mathbf{R}^{m \times n}$, $b, y \in \mathbf{R}^m$, $c, x, s \in \mathbf{R}^n$, and x, y, s are the vectors of variables. Without loss of generality we assume that $\text{rank}(A) = m$.

From the article titled **Central Path and Barrier Algorithms for Linear Optimization** in this encyclopedia, it is clear that one can solve (P) and (D) by an interior-point method (IPM) if we know a triple (x, y, s) such that x is feasible for (P) and (y, s) is feasible for (D) and moreover this triple is close enough to the central path of (P) and (D). In general, such a triple is not a priori known and, even worse, it may not exist. The latter case occurs when one of the two problems is infeasible, or when both problems are feasible and the central path does not exist, that is, when the problems are not strictly feasible. This raises the question how IPMs can be used to solve an LO problem in such a case.

Recall that a similar issue arises when solving an LO problem with the simplex method. In order to solve (P) with the primal simplex method, one needs a vertex solution of the primal problem and, similarly, to solve (D) with the dual simplex method,

one needs a vertex solution of the dual problem. For the simplex method this problem has been resolved in several ways. The most common method is the so-called *two-phase method*. In phase 1, one solves an auxiliary problem which yields a vertex solution or detects infeasibility of the given problem. If phase 1 yields a vertex solution then phase 2 starts the simplex method at this vertex and either finds an optimal solution or detects that the problem is unbounded. In this way, a two-phase simplex method can solve any LO problem: it finds an optimal solution of the given problem or, if no optimal solution exists, it detects infeasibility or unboundedness. Other methods solve the problem in one phase (i.e., without first solving an auxiliary problem) by adding a term to the objective with a big coefficient M of an auxiliary variable that vanishes if the given problem has an optimal solution, provided that such a solution exists and M is large enough. For details, the reader could refer to the section titled "Optimization Models, Techniques, and Algorithms" in this encyclopedia. It might be mentioned that there also exists a one-phase simplex method that does not use an additional variable nor a big M . This so-called *criss-cross method* is less well-known, but interesting in itself. It uses both primal and dual pivoting operations, and solves a given problem in finitely many steps. For details, the reader could refer to Ref. 1.

The initialization problem for IPMs also has been resolved in several ways. Most common are so-called *infeasible start methods*, which are efficient and most popular. These methods start with an arbitrary infeasible triple (x^0, y^0, s^0) with $x^0 > 0$ and $s^0 > 0$ and reduce the infeasibility with about the same speed as the duality gap until both fall below some prescribed accuracy. They were developed and analyzed by Lustig [2], Kojima *et al.* [3], Mizuno [4], Mizuno *et al.* [5], Potra [6,7], Tanabe [8], Wright [9], Zhang [10]. Only few of these methods have polynomial iteration bounds, namely, Refs 4 and 10. The best of these bounds (in Ref. 4) is a factor $\sqrt{n}$ worse.

In this section, we present a different approach that was proposed first by Ye *et al.* [14] and is based on a homogeneous self-dual model introduced much earlier by Goldman and Tucker [15,16]. The given LO problem and its dual problem are embedded in such a model, while using two extra variables and two extra constraints. The model is such that it has a central path and moreover, the point corresponding to $\mu = 1$ on the central path is known. Starting from this point the model can be solved by any path-following IPM. Thus the generated optimal solution of the model yields in a simple way optimal solutions of the given problem and its dual if these exist. Otherwise, it yields a certificate that guarantees infeasibility of at least one of the two problems. Each iteration requires the solution of a system of linear equations, whose dimension is almost the same as for the primal-dual method in the article titled **Central Path and Barrier Algorithms for Linear Optimization** in this encyclopedia, whereas the number of iterations is of the same order.

Notations

The set of real numbers is denoted as $\mathbf{R}$. $\mathbf{R}^n$, and $\mathbf{R}_+^n$ denote the set of real vectors of length n and its subset of nonnegative vectors, respectively. The zero vector and all-one vector in $\mathbf{R}^n$ are denoted as 0_n and e_n , respectively; if this gives no rise to confusion, we drop the subscript and simply write 0 or e . If f is a univariate function then, $f(x)$ is the vector with coordinates $f(x_i)$. This defines, for example, for any positive vector the vectors x^2 , x^{-1} , and $\sqrt{x}$. To any vector $x \in \mathbf{R}^n$, we associate the diagonal matrix X whose diagonal entries are the elements of x , in the same order. If also $s \in \mathbf{R}^n$, then Xs will be denoted shortly as xs . So xs is the so-called *Hadamard product*: its entries are obtained by componentwise multiplication of x and s . Finally, if s is positive then we denote xs^{-1} also as x/s .

REFORMULATION (P') OF (P)

The input data for the problems (P) and (D) consists of the triple (A, b, c) , where A is an

$m \times n$ matrix, $b \in \mathbf{R}^m$, and $c \in \mathbf{R}^n$. As before, we assume without loss of generality that $\text{rank}(A) = m$. First, we replace (P) by an equivalent problem that has only inequality constraints. In order to do this, we choose an arbitrary basis of A . So let B denote a subset of m indices in $\{1, \dots, n\}$ such that the columns of A indexed by these indices form a nonsingular $m \times m$ matrix. Since A has full row rank, this is possible. We denote the basis consisting of the columns of A indexed by B as A_B . Again, without loss of generality, we assume that A_B consists of the first m columns of A . Then we may write

$$A = [A_B \ A_N],$$

where A_N has size $m \times (n - m)$, with N consisting of the indices outside B . We then have

$$\begin{aligned} Ax = b &\Leftrightarrow A_B x_B + A_N x_N = b \\ &\Leftrightarrow x_B = A_B^{-1}(b - A_N x_N), \end{aligned} \quad (1)$$

where x_B denotes the restriction of x to its first m entries and x_N is the remaining part of x . Defining c_B and c_N in a similar way, we have

$$\begin{aligned} c^T x &= c_B^T x_B + c_N^T x_N \\ &= c_B^T A_B^{-1}(b - A_N x_N) + c_N^T x_N \\ &= c_B^T A_B^{-1} b + (c_N^T - c_B^T A_B^{-1} A_N) x_N. \end{aligned}$$

It follows that (P) can be reformulated as follows:

$$\begin{aligned} \min \{ &c_B^T A_B^{-1} b + (c_N^T - c_B^T A_B^{-1} A_N) x_N : \\ &A_B^{-1}(b - A_N x_N) \geq 0, x_N \geq 0 \}. \end{aligned}$$

Given an optimal solution x_N of this problem, an optimal solution $x = [x_B; x_N]$ of (P) is obtained by computing x_B from Equation (1). Omitting the constant term $c_B^T A_B^{-1} b$ in the objective, and redefining A , b , c , and x according to

$$\begin{aligned} A &:= -A_B^{-1} A_N, \quad b := -A_B^{-1} b, \\ c &:= (c_N^T - c_B^T A_B^{-1} A_N)^T = c_N^T - A_N^T A_B^{-T} c_B, \\ x &:= x_N, \end{aligned}$$

we can equally well solve the problem

$$\min\{c^T x : Ax \geq b, x \geq 0\}. \quad (P')$$

Now A has size $m \times (n - m)$, $b \in \mathbf{R}^m$, and $c \in \mathbf{R}^{n-m}$. The dual problem is given by

$$\max\{b^T y : A^T y \leq c, y \geq 0\}. \quad (D')$$

In the next section, we embed this primal-dual pair of problems in an artificial self-dual LO problem.

EMBEDDING (P') AND (D') IN A SELF-DUAL PROBLEM (SP)

We introduce two new variables, κ and ϑ , and consider the following problem

$$\begin{aligned} \min \quad & \bar{n}\vartheta \\ \text{s.t.} \quad & Ax - b\kappa + \bar{b}\vartheta \geq 0, \\ & -A^T y + b^T y + c\kappa + \bar{c}\vartheta \geq 0, \\ & b^T y - c^T x + z\vartheta \geq 0, \\ & -\bar{b}^T y - \bar{c}^T x - \bar{z}\kappa \geq -\bar{n}, \\ & y \geq 0, x \geq 0, \kappa \geq 0, \vartheta \geq 0, \end{aligned} \quad (SP)$$

where

$$\begin{aligned} \bar{b} &= e_m + b - Ae_{n-m}, \quad \bar{c} = e_{n-m} + A^T e_m - c, \\ \bar{z} &= 1 - b^T e_m + c^T e_{n-m}, \quad \bar{n} = n + 2. \end{aligned}$$

Lemma 1. *If (SP) has a feasible solution $(y, x, \kappa, \vartheta)$ with $\kappa > 0$ and $\vartheta = 0$ then x/κ is optimal for (P') and y/κ for (D'). Otherwise, (P') and (D') have no optimal solutions.*

Proof. First, observe that if (P') has an optimal solution x^* then, by the Duality Theorem for an LO, (D') has also an optimal solution (y^*, s^*) and $b^T y^* = c^T x^*$ (see **LP Duality and KKT Conditions for LP**). Then, one may easily verify that $(y^*, x^*, 1, 0)$ satisfies the first three constraints in (SP). If $\bar{b}^T y^* + \bar{c}^T x^* + \bar{z} \leq 0$ then also the fourth constraint is satisfied. Otherwise, if $\bar{b}^T y^* + \bar{c}^T x^* + \bar{z} > 0$, we may find $\lambda > 0$ such that $\lambda(y^*, x^*, 1, 0)$ satisfies all constraints. Hence, we conclude that if (P') and (D') have optimal solutions then

(SP) has a feasible solution with $\vartheta = 0$ and $\kappa > 0$.

We now show that the converse is also true. Note that if $\kappa = 1$ and $\vartheta = 0$ then the first constraint and $x \geq 0$ represent primal feasibility and the second constraint and $y \geq 0$ represent dual feasibility. The third constraint then requires $b^T y - c^T x \geq 0$. However, since x is primal feasible and y dual feasible, we also have the converse inequality, because $c^T x \geq b^T y$ holds by the weak duality property. So it follows that $c^T x = b^T y$. Hence any feasible solution of (SP) with $\kappa = 1$ and $\vartheta = 0$ yields optimal solutions of (P') and (D'). A quite similar argument yields an even stronger result which is crucial for our purpose, namely that any feasible solution with $\kappa > 0$ and $\vartheta = 0$ yields optimal solutions of (P') and (D'). This easily follows from the fact that the first three constraints are homogeneous. Therefore, if $(y, x, \kappa, \vartheta = 0)$ is feasible for these constraints and $\kappa > 0$, then so is $(y/\kappa, x/\kappa, 1, \vartheta = 0)$, yielding that x/κ is optimal for (P') and y/κ for (D').

To proceed, we need to consider (SP) in more detail. Defining

$$M := \begin{bmatrix} 0 & A & -b & \bar{b} \\ -A^T & 0 & c & \bar{c} \\ b^T & -c^T & 0 & \bar{z} \\ -\bar{b}^T & -\bar{c}^T & -\bar{z} & 0 \end{bmatrix},$$

$$z := \begin{bmatrix} y \\ x \\ \kappa \\ \vartheta \end{bmatrix}, \quad q := \begin{bmatrix} 0 \\ 0 \\ 0 \\ \bar{n} \end{bmatrix},$$

we can reformulate (SP) as follows:

$$\min \left\{ q^T z : Mz \geq -q, z \geq 0 \right\}.$$

When writing down the dual of this problem, we get

$$\max \left\{ -q^T w : M^T w \leq q, w \geq 0 \right\}.$$

Now observe that the matrix M is skew-symmetric, that is, $M^T = -M$. Therefore, we may replace $M^T w \leq q$ by $-Mw \leq q$, which is the same as $Mw \geq -q$. This makes clear that (SP) and its dual have the same domain and the same objective. We conclude that the dual

problem is the same problem as (SP). This is expressed by saying that the problem (SP) is self-dual. Since the vector q is nonnegative and $z \geq 0$, we have $q^T z \geq 0$ showing that the objective values of (SP) are nonnegative. Since the zero vector is feasible for (SP), it follows that the optimal value is zero. We conclude that a feasible vector $z = (y, x, \kappa, \vartheta)$ is optimal if and only if $\vartheta = 0$. Combining this observation with Lemma 1, we obtain the following lemma.

Lemma 2. *If (SP) has an optimal solution $(y, x, \kappa, \vartheta)$ with $\kappa > 0$ then x/κ is optimal for (P) and y/κ for (D'). Otherwise, (P) and (D') have no optimal solutions.*

The next question is whether we can discover if an optimal solution of (SP) exists with $\kappa > 0$. As we show in the rest of this section, the answer is positive and any IPM can do this for us.

THE CENTRAL PATH OF (SP)

First, we need to show that the central path of (SP) exists. In order to do this, we need to write down the KKT system, as given in the article titled **Central Path and Barrier Algorithms for Linear Optimization** in this encyclopedia, which determines the μ -center on the central path. To this end, we introduce a slack vector $s = Mz + q$ and write (SP) in the primal standard form, that is, as a minimization problem with equality constraints and nonnegative v

$$\min \left\{ \begin{bmatrix} q \\ 0 \end{bmatrix}^T \begin{bmatrix} z \\ s \end{bmatrix} : \begin{bmatrix} M & -I \end{bmatrix} \begin{bmatrix} z \\ s \end{bmatrix} = -q, \begin{bmatrix} z \\ s \end{bmatrix} \geq 0 \right\}.$$

With w denoting the vector of dual variables, the dual of this problem is given by

$$\max \left\{ -q^T w : \begin{bmatrix} -M \\ -I \end{bmatrix} w \leq \begin{bmatrix} q \\ 0 \end{bmatrix} \right\}.$$

Introducing slack vectors u and v for the dual constraints these get the form $-Mw + u = q$ and $-w + v = 0$. Now we can write down the KKT system for the current case, which

consists of the primal and dual feasibility conditions and the centering conditions. Thus, it becomes clear that the central path of (SP) exists if and only if the following system has a solution for at least one positive value of μ

$$\begin{aligned} Mz - s &= -q, & z \geq 0, s \geq 0, \\ -Mw + u &= q, & u \geq 0, \\ -w + v &= 0, & v \geq 0, \\ uz &= \mu e, \\ vs &= \mu e. \end{aligned}$$

Due to the third equation, we can eliminate w from the system. This yields the equivalent system

$$\begin{aligned} Mz - s &= -q, & z \geq 0, s \geq 0, \\ Mv - u &= -q, & u \geq 0, v \geq 0, \\ zu &= \mu e, \\ vs &= \mu e. \end{aligned}$$

Since the KKT system represents the first order optimality conditions for the primal logarithmic barrier function, and this function is strictly convex, the system has at most one solution. One easily sees that this implies that any solution will satisfy $v = z$ and $u = s$. Thus, we may conclude that the KKT system for (SP) has a solution if and only if the much simpler system

$$Mz - s = -q, \quad z \geq 0, s \geq 0, \quad (2)$$

$$zs = \mu e, \quad (3)$$

has a solution for some $\mu > 0$.

To prove the existence of the central path of (SP), it remains to show that this system has a solution for at least one positive value of μ . Due to the construction of (SP), this is now surprisingly easy. We claim that $z = e_{\bar{n}}$, $s = e_{\bar{n}}$, and $\mu = 1$ satisfy our goal. Indeed, taking $y = e_m$, $x = e_{n-m}$, $\kappa = 1$, and $\vartheta = 1$,

we get

$$\begin{aligned}
 Me_{\bar{n}} &= \begin{bmatrix} 0 & A & -b & \bar{b} \\ -A^T & 0 & c & \bar{c} \\ b^T & -c^T & 0 & \bar{z} \\ -\bar{b}^T & -\bar{c}^T & -\bar{z} & 0 \end{bmatrix} \begin{bmatrix} e_m \\ e_{n-m} \\ 1 \\ 1 \end{bmatrix} \\
 &= \begin{bmatrix} Ae_{n-m} - b + \bar{b} \\ -A^T e_m + c + \bar{c} \\ b^T e_m - c^T e_{n-m} + \bar{z} \\ -\bar{b}^T e_m - \bar{c}^T e_{n-m} - \bar{z} \end{bmatrix} = \begin{bmatrix} e_m \\ e_{n-m} \\ 1 \\ 1 - \bar{n} \end{bmatrix} \\
 &= e_{\bar{n}} - q,
 \end{aligned}$$

where we used the definitions of $\bar{b}$, $\bar{c}$, and $\bar{z}$. The following lemma summarizes the results of this section.

Lemma 3. (SP) has a central path and the μ -center is determined by the system (2)–(3). Moreover, $Me_{\bar{n}} + q = e_{\bar{n}}$, which implies that the 1-center is given by $s = z = e_{\bar{n}}$.

Of course, this lemma is of utmost importance. It means that we can solve (SP) by any IPM, because we can start any such method (primal, dual, or primal-dual) at the 1-center!

It might be no surprise that due to the self-duality the search directions in a primal-dual method for solving (SP) are obtained from a much simpler system than in the general case. They are determined by the following system:

$$M\Delta z - \Delta s = 0, \quad (4)$$

$$z\Delta s + s\Delta z = \mu e - zs. \quad (5)$$

One may easily check this by linearizing the KKT system for (SP) and its dual.

On the other hand, also due to self-duality, the primal method and the dual method are exactly the same methods. We leave it to the reader to verify that the search directions are then determined by the following system:

$$M\Delta z - \Delta s = 0, \quad (6)$$

$$(Z^{-2} + MS^{-2}M^T)\Delta z = z^{-1} - Ms^{-1} - \mu^{-1}q. \quad (7)$$

Note that we can solve Δz from Equation (7); since the matrix $Z^{-2} + MS^{-2}M^T$ is positive

definite the solution exists and is unique. Then Δs follows from Equation (6). Note that since $q = s - Mz$, the right-hand side expression in Equation (7) can be written as

$$z^{-1} - \mu^{-1}s - M(s^{-1} - \mu^{-1}z).$$

One easily verifies that this expression vanishes if $zs = \mu e$, that is, if $z = z(\mu)$ (and $s = s(\mu)$). This makes clear that at the μ -center, the primal search direction vanishes, as it should. In that case the primal direction coincides with the primal-dual direction, but otherwise they will (in general) be different.

We proceed with another important consequence of Lemma 3.

Lemma 4. If $z = (y, x, \kappa, \vartheta)$ is feasible for (SP) and $s = Mz + q$ then

$$e_{\bar{n}}^T z + e_{\bar{n}}^T s = \bar{n} + q^T z = \bar{n}(1 + \vartheta).$$

Proof. Since M is skew-symmetric, we have

$$a^T M a = 0, \quad \forall a \in \mathbf{R}^{\bar{n}}. \quad (8)$$

We call this the *orthogonality property*. By taking $a = e_{\bar{n}} - z$, it follows that

$$\begin{aligned}
 0 &= (e_{\bar{n}} - z)^T M(e_{\bar{n}} - z) = (e_{\bar{n}} - z)^T (Me_{\bar{n}} - Mz) \\
 &= (e_{\bar{n}} - z)^T (e_{\bar{n}} - s).
 \end{aligned}$$

Since $e_{\bar{n}}^T e_{\bar{n}} = \bar{n}$ and

$$z^T s = z^T (Mz + q) = q^T z = \bar{n}\vartheta, \quad (9)$$

this implies the lemma.

We just established that $q^T z = z^T s = \bar{n}\vartheta$. On the other hand, if $z = z(\mu)$ and $s = s(\mu)$ then Equation (3) implies $z^T s = \bar{n}\mu$. Thus, it follows that on the central path one has $\vartheta = \mu$. Since $\vartheta = z_{\bar{n}}$ and $z_{\bar{n}}s_{\bar{n}} = \mu$, it follows that $s_{\bar{n}} = 1$ along the central path.

OPTIMAL PARTITION OF (SP)

The question that still remains is whether we can decide if (SP) has an optimal solution with $\kappa > 0$. To answer this question, we need some extra notions and notations. First, for any $z \in \mathbf{R}^{\bar{n}}$, we define $s(z) = Mz + q$. Then z is feasible for (SP) if and only if z and $s(z)$ are nonnegative, and z is optimal if moreover $zs(z) = 0$. The latter means that z and $s(z)$ are complementary vectors, because for each index i , either $z_i = 0$ or $s_i(z) = 0$. If moreover for each i one of z_i and $s_i(z)$ is positive, we say that z and $s(z)$ are strictly complementary vectors, or shortly, that z is a strictly complementary optimal solution.

We now define index sets B and N as follows:

$$\begin{aligned} B &:= \{i : z_i > 0 \text{ for some optimal solution } z\}, \\ N &:= \{i : s_i(z) > 0 \\ &\quad \text{for some optimal solution } z\}. \end{aligned}$$

So, B contains all indices i for which an optimal solution z with positive z_i exists. We also write $z_i \in B$ if $i \in B$. Note that we certainly have $\vartheta \notin B$ because $\vartheta = 0$ for any optimal solution. The main question that we need to answer is whether $\kappa \in B$ holds or not. Because if $\kappa \in B$, then there exists an optimal solution z with $\kappa > 0$, in which case (P') and (D') have optimal solutions and not otherwise.

The next lemma implies that the sets B and N are disjoint.

Lemma 5. *Let z^1 and z^2 be feasible for (SP). Then z^1 and z^2 are optimal solutions of (SP) if $z^1 s(z^2) = z^2 s(z^1) = 0$.*

Proof. Due to the orthogonality property (8), we have

$$(z^1 - z^2)^T M(z^1 - z^2) = 0,$$

which implies

$$(z^1 - z^2)^T (s(z^1) - s(z^2)) = 0.$$

Expanding the product on the left and rearranging the terms, we get

$$\begin{aligned} (z^1)^T s(z^2) + (z^2)^T s(z^1) &= (z^1)^T s(z^1) \\ &\quad + (z^2)^T s(z^2). \end{aligned}$$

Now, z^1 is optimal if $(z^1)^T s(z^1) = 0$ and, similarly, z^2 is optimal if $(z^2)^T s(z^2) = 0$. Hence, since $z^1, z^2, s(z^1)$ and $s(z^2)$ are all nonnegative, z^1 and z^2 are optimal if

$$(z^1)^T s(z^2) + (z^2)^T s(z^1) = 0,$$

which is equivalent to

$$z^1 s(z^2) = z^2 s(z^1) = 0,$$

proving the lemma.

By a relatively old result of Goldman and Tucker [15], every LO problem has a strictly complementary optimal solution, which implies that $B \cup N = \{1, \dots, \bar{n}\}$. Owing to Lemma 5, the sets B and N are disjoint. Hence they form a partition of the index set $\{1, \dots, \bar{n}\}$. We call this the *optimal partition* of (SP). It should be clear now that the question whether there exists an optimal solution with $\kappa > 0$ is completely answered as soon as we know the optimal partition of (SP).

FINDING THE OPTIMAL PARTITION OF (SP)

We show, in this section, that if some feasible z is close enough to the μ -center, and μ is small enough, then we can recognize the optimal partition (B, N) from z . We also show that such a z can be found in a number of iterations that depends only on the dimension $\bar{n}$ and on a condition number σ_{SP} of (SP). The condition number is defined by

$$\sigma_{SP} := \min_{1 \leq i \leq \bar{n}} \max_{z \in SP^*} \{z_i + s_i(z)\},$$

where SP^* denotes the set of optimal solutions of (SP). Recall that if z is optimal then either $z_i = 0$ or $s_i(z) = 0$, for each i . For a strictly complementary solution, we have $z_i + s_i(z) > 0$ for each i . Hence, the maximum in the above definition is always positive. Therefore, being the minimum of a finite set of positive numbers, σ_{SP} is positive as well. Also, by Lemma 4, then $e^T z + e^T s(z) = \bar{n}$ for each $z \in SP^*$; this implies that the average value of $z_i + s_i(z)$ equals 1.

To proceed, we need a simple measure for the distance of any strictly feasible z to the central path. For that purpose, we define the number $\delta_c(z)$ as follows:

$$\delta_c(z) := \frac{\max(zs(z))}{\min(zs(z))}. \quad (10)$$

Observe that $\delta_c(z) = 1$ if $zs(z)$ is a multiple of the all-one vector e . Obviously, this occurs precisely if z lies on the central path. Otherwise, we have $\delta_c(z) > 1$. We consider $\delta_c(z)$ as an indicator for the “distance” of z to the central path.

Lemma 6. *Let z be a feasible solution of (SP) such that $\delta_c(z) \leq \tau$. Then, with $s = s(z)$, we have*

$$\begin{aligned} z_i &\geq \frac{\sigma_{SP}}{\tau \bar{n}}, \quad i \in B, & z_i &\leq \frac{z^T s}{\sigma_{SP}}, \quad i \in N, \\ s_i &\leq \frac{z^T s}{\sigma_{SP}}, \quad i \in B, & s_i &\geq \frac{\sigma_{SP}}{\tau \bar{n}}, \quad i \in N. \end{aligned}$$

Proof. From $\delta_c(z) \leq \tau$, we conclude that there exist positive numbers τ_1 and τ_2 such that $\tau \tau_1 = \tau_2$ and

$$\tau_1 \leq z_i s_i \leq \tau_2, \quad 1 \leq i \leq \bar{n}. \quad (11)$$

First, suppose that $i \in N$. Let $\tilde{z}$ be an optimal solution such that $\tilde{s}_i := s_i(\tilde{z})$ is maximal. Then $\tilde{z}_i = 0$ and the definition of σ_{SP} implies that $\tilde{s}_i \geq \sigma_{SP}$. Applying the orthogonality property to the points $\tilde{z}$ and z , we obtain $(\tilde{z} - z)^T(\tilde{s} - s) = 0$. Since $\tilde{z}$ is optimal, we have $\tilde{z}^T \tilde{s} = 0$. Hence we obtain

$$z^T \tilde{s} + s^T \tilde{z} = z^T s.$$

Since all involved vectors are nonnegative and $z_i \tilde{s}_i \leq z^T \tilde{s}$, we therefore may write

$$z_i \tilde{s}_i \leq z^T \tilde{s} \leq z^T s.$$

Hence, dividing by $\tilde{s}_i$ and using $\tilde{s}_i \geq \sigma_{SP} > 0$, we get

$$z_i \leq \frac{z^T s}{\sigma_{SP}}.$$

From the left inequality in Equation (11) we also have $z_i s_i \geq \tau_1$. Hence, it follows that

$$s_i \geq \frac{\tau_1 \sigma_{SP}}{z^T s}.$$

The right inequality in Equation (11) gives $z^T s \leq \bar{n} \tau_2$. Therefore

$$s_i \geq \frac{\tau_1 \sigma_{SP}}{\bar{n} \tau_2} = \frac{\sigma_{SP}}{\bar{n} \tau}.$$

This proves the second and fourth inequality in the lemma. The other inequalities are obtained in a similar way. If $i \in B$ and $\tilde{z}$ is an optimal solution such that $\tilde{z}_i$ is maximal, then $\tilde{z}_i \geq \sigma_{SP}$. Now applying the orthogonality property to the points $\tilde{z}$ and z , we obtain

$$s_i \tilde{z}_i \leq s^T \tilde{z} \leq z^T s.$$

Thus we get

$$s_i \leq \frac{z^T s}{\tilde{z}_i} \leq \frac{z^T s}{\sigma_{SP}}.$$

Using once more that $z_i s_i \geq \tau_1$ and $z^T s \leq \bar{n} \tau_2$, we obtain

$$z_i \geq \frac{\tau_1 \sigma_{SP}}{z^T s} \geq \frac{\tau_1 \sigma_{SP}}{\bar{n} \tau_2} = \frac{\sigma_{SP}}{\bar{n} \tau},$$

completing the proof of the lemma.

The results of the above lemma are summarized in Table 1.

We conclude that if $z^T s$ is so small that

$$\frac{z^T s}{\sigma_{SP}} < \frac{\sigma_{SP}}{\tau \bar{n}},$$

then we have a complete separation of the variables in B and the variables in N . Thus, we may state without further proof the following result.

Table 1. Estimates for the Variables in B and in N if $\delta_c(z) \leq \tau$

	$i \in B$	$i \in N$
z_i	$\geq \frac{\sigma_{SP}}{\tau \bar{n}}$	$\leq \frac{z^T s}{\sigma_{SP}}$
$s_i(z)$	$\leq \frac{z^T s}{\sigma_{SP}}$	$\geq \frac{\sigma_{SP}}{\tau \bar{n}}$

Lemma 7. *Let z be a feasible solution of (SP) such that $\delta_c(z) \leq \tau$. If*

$$z^T s(z) < \frac{\sigma_{SP}^2}{\tau \bar{n}},$$

then the optimal partition of (SP) follows from

$$B = \{i : z_i > s_i(z)\} \quad \text{and} \quad N = \{i : z_i < s_i(z)\}. \quad (12)$$

In the subsequent analysis, we need to find an upper bound τ for the values of $\delta_c(z)$ during the course of the algorithm. It can be shown that after each iteration of the primal and the dual method, one has $\delta_c(z) \leq (7 + \sqrt{7})/(7 - \sqrt{7}) \approx 2.215250$. Below we focus on the use of the primal-dual method. In that case, one has $\delta_c(z) \leq 4$ after each iteration, as follows from the next lemma. In this lemma, we use the vector v defined by

$$v := \frac{\sqrt{zs(z)}}{\mu} \quad (13)$$

and we use that after each iteration of the primal-dual IPM, as presented in the article titled **Central Path and Barrier Algorithms for Linear Optimization** in this encyclopedia, one has $\delta(zs(z), \mu) \leq \frac{1}{2}$, where

$$\delta(zs(z), \mu) := \frac{1}{2} \|v^{-1} - v\|. \quad (14)$$

Lemma 8. *If $\delta(zs(z), \mu) \leq \frac{1}{2}$ then $\delta_c(z) \leq 4$.*

Proof. Using the vector v of z , with respect to the given $\mu > 0$, we have $zs(z) = \mu v^2$. Hence, we may write

$$\delta_c(z) = \frac{\max(\mu v^2)}{\min(\mu v^2)} = \frac{\max(v^2)}{\min(v^2)}.$$

Due to the definition (14) of $\delta(zs(z), \mu)$, it follows that

$$\|v - v^{-1}\| \leq 1.$$

Without loss of generality, we assume that the coordinates of v are ordered such that $v_1 \geq v_2 \geq \dots \geq v_n$. Then $\delta_c(z) = v_1^2/v_n^2$. Now consider the problem

$$\max \left\{ \frac{v_1^2}{v_n^2} : \|v - v^{-1}\| \leq 1 \right\}.$$

The optimal value of this problem is an upper bound for $\delta_c(z)$. One may easily verify that the optimal solution has $v_i = 1$ if $1 < i < \bar{n}$, $v_1 = \sqrt{2}$, and $v_{\bar{n}} = 1/\sqrt{2}$. Hence the optimal value is 4. This proves the lemma.

The above lemma is the basis of our next result, based on the use of the primal-dual algorithm. One easily derives a similar result for the primal method by using $\tau = 2.215250$.

Theorem 1. *After at most*

$$\left\lceil \sqrt{2\bar{n}} \log \frac{4\bar{n}^2}{\sigma_{SP}^2} \right\rceil \quad (15)$$

iterations the primal-dual algorithm yields a strictly feasible solution z of (SP) that reveals the optimal partition (B, N) of (SP) according to Equation (12).

Proof. Let us run the primal-dual algorithm with $\varepsilon = \sigma_{SP}^2/4\bar{n}$. Then, Theorem 3 in the article titled **Central Path and Barrier Algorithms for Linear Optimization** in this encyclopedia guarantees that we obtain a strictly feasible z with $z^T s(z) \leq \sigma_{SP}^2/4\bar{n}$ and $\delta(zs(z), \mu) \leq 1/2$. Lemma 8 implies that $\delta_c(z) \leq 4$. By Lemma 7, with $\tau = 4$, this z provides us the classes B and N of the optimal partition, according to (12). Using Theorem 3 in article titled **Central Path and Barrier Algorithms for Linear Optimization** in this encyclopedia again, we obtain that the required number of iterations for the given ε is at most

$$\left\lceil \sqrt{2\bar{n}} \log \frac{4\bar{n}^2}{\sigma_{SP}^2} \right\rceil,$$

which is precisely the bound given in the theorem. This completes the proof.

FINAL REMARKS

We conclude from Theorem 1 that the decision about the existence of an optimal solution with $\kappa > 0$ can be made safely if we run the primal-dual algorithm with $\varepsilon \leq \sigma_{SP}^2/(4\bar{n})$. The weakness of this result is that we do not know the condition number σ_{SP} . Its computation is at least as demanding

as solving (SP). It should be mentioned that if the entries of M are integral then we have the following easily computable lower bound for the condition number

$$\sigma_{SP} \geq \frac{1}{\prod_{j=1}^n \|M_j\|}, \quad (16)$$

where M_j denotes the j th column of M [17, Theorem I.42].

Another important consequence of the above analysis is that if ε is small enough, eventually the iterates converge to a strictly complementary solution of (SP). This follows from Table 1: the B -part of z and the N -part of $s(z)$ stay bounded away from zero. These iterate are still not exact solutions, because they remain strictly feasible. However, there exists a polynomial-time rounding procedure that yields an exact solution, provided that ε is small enough. For details, the reader could refer to Ref. 17, Section 3.3.5.

If $\kappa \in B$ then we know from Lemma 2 that, and how, optimal solutions of (P') and (D') can be obtained. If it turns out that $\kappa \in N$, then the same lemma implies that (P') and (D') do not have optimal solutions. We finally want to show that the output of the algorithm then provides a certificate for this fact.

If $\kappa \in N$, that is, if $\kappa = 0$, then the strict complementarity of z implies that the entry of $s(z)$ corresponding to κ belongs to B . This entry is the slack value of the third constraint in the original version of (SP), which means that this entry of $s(z)$ is given by $b^T y - c^T x$, since $\vartheta = 0$. So $b^T y - c^T x > 0$. It also follows from $\kappa = 0$ and $\vartheta = 0$ that $Ax \geq 0$ and $-A^T y \geq 0$. We conclude that if $\kappa \in N$ then we have x and y such that

$$\begin{aligned} b^T y - c^T x > 0, \quad Ax \geq 0, \quad A^T y \leq 0, \quad x \geq 0, \\ y \geq 0. \end{aligned} \quad (17)$$

The first inequality implies that either $b^T y > 0$ or $c^T x < 0$. If $b^T y > 0$ then (P') (and hence also (P)) is infeasible, since by assuming that $\bar{x}$ is primal feasible, we obtain

$$0 \geq \bar{x}^T A^T y = (A\bar{x})^T y = b^T y,$$

a contradiction. On the other hand, if $c^T x < 0$ then (D') is infeasible, since if $\bar{y}$ is dual feasible, we obtain

$$0 \leq \bar{y}^T Ax = (A^T \bar{y})^T x \leq c^T x,$$

again a contradiction.

Thus, we have shown that $\kappa \in N$ is a certificate for either (P') or (D') being infeasible. We know from the Duality Theorem for LO that if (P') and (D') do not have optimal solutions then there are three possibilities: (i) (P') infeasible and (D') unbounded, (ii) (P') unbounded and (D') infeasible, or (iii) (P') infeasible and (D') infeasible. Unfortunately, our certificate does not inform us about which of these three cases occur. It is still an open question whether a simple certificate exists that requires no additional computational effort and that yields information on which of the three possible cases occurs if $\kappa = 0$.

SEMIDEFINITE OPTIMIZATION APPLICATIONS

ANTHONY MAN-CHO SO

Kong, Hong Kong, China

INTRODUCTION

Recently, semidefinite programming (SDP) has received a lot of attention in many communities. Such a popularity can partly be attributed to the wide applicability of SDP, as well as recent advances in the design of provably efficient interior-point algorithms and fast heuristics. In this article, we will survey some of the recent applications of SDP and provide further pointers to the literature for interested readers. Given the versatile modeling power of SDPs and the multitude of work that applies the SDP methodology, we should emphasize that the applications discussed in this article are by no means exhaustive, and they necessarily reflect a certain degree of personal bias.

Before we begin our discussion on SDP applications, let us fix some notation. Let $\mathbb{S}^n$ be the set of $n \times n$ real, symmetric matrices, and let $\mathbb{S}_+^n \subset \mathbb{S}^n$ be the set of $n \times n$ real, symmetric, positive semidefinite matrices, that is, if $A \in \mathbb{S}_+^n$, then for any $x \in \mathbb{R}^n$, we have $x^T A x \geq 0$. We shall also write $A \succeq \mathbf{0}$ to denote the fact that $A \in \mathbb{S}_+^n$. For any $A, B \in \mathbb{S}^n$, we define the *trace inner product* $A \bullet B$ via

$$A \bullet B = \text{tr}(A^T B) = \sum_{i,j=1}^n A_{ij} B_{ij}.$$

Let $C, A_1, \dots, A_m \in \mathbb{S}^n$ and $b \in \mathbb{R}^m$. The optimization problem

$$\begin{aligned} & \inf \quad C \bullet X \\ \text{(P): subject to} \quad & A_i \bullet X = b_i \quad \text{for } 1 \leq i \leq m, \\ & X \succeq \mathbf{0} \end{aligned}$$

is called an *SDP in primal standard form*. Its dual problem, which is given by

$$\begin{aligned} & \sup \quad b^T y \\ \text{(D): subject to} \quad & \sum_{i=1}^m y_i A_i + Z = C, \\ & y \in \mathbb{R}^m, Z \succeq \mathbf{0}, \end{aligned}$$

is also an SDP and is called an *SDP in dual standard form*. Theoretically, it has been shown that both (P) and (D) can be efficiently solved (up to any desired degree of accuracy) by the ellipsoid method or interior-point algorithms [1,2]. Many techniques have also been recently developed to speed up the solution time of SDPs [3–5].

In the sequel, we shall see how (P) and (D) can be used to model a wide range of problems that arise in practice.

SEMIDEFINITE RELAXATIONS OF HARD QUADRATIC OPTIMIZATION PROBLEMS

The Basic Technique

A frequently used and powerful idea for dealing with hard optimization problems is to develop tractable convex relaxations of them. As it turns out, many difficult quadratic optimization problems can be relaxed to SDPs. To illustrate some of the basic ideas, let us consider the following class of homogeneous *quadratically constrained quadratic programs* (QCQPs):

$$\begin{aligned} & \text{minimize} \quad x^T A x \\ \text{(QCQP): subject to} \quad & x^T A_i x \succeq_i b_i, \\ & x \in \mathbb{R}^n, \\ & \text{where } i = 1, \dots, m. \end{aligned}$$

Here, we assume that $A, A_1, \dots, A_m \in \mathbb{S}^n$ and $b_1, \dots, b_m \in \mathbb{R}$, and “ $\succeq_i$ ” can represent either “ $\geq$,” “ $=$,” or “ $\leq$,” where $i = 1, \dots, m$. Problem (QCQP) is known to be NP-hard, as it captures various NP-hard problems as special cases [6–8]. To derive an SDP relaxation of (QCQP), we first observe that

$$x^T A x = A \bullet x x^T \quad \text{and} \quad x^T A_i x = A_i \bullet x x^T \\ \text{for } i = 1, \dots, m.$$

In particular, both the objective function and constraints in (QCQP) are *linear* in the matrix $x x^T$. Thus, by introducing a new variable $X = x x^T$ that denotes a rank one symmetric positive semidefinite matrix, we obtain the following *equivalent* formulation of (QCQP):

$$\begin{aligned} (\text{QCQP-RC}) : \\ \text{minimize} \quad & A \bullet X \\ \text{subject to} \quad & A_i \bullet X \geq b_i, \\ & X \succeq 0, \quad \text{rank}(X) = 1, \\ \text{where } i = & 1, \dots, m. \end{aligned}$$

The upshot of the above equivalent formulation is that it allows us to identify the fundamental difficulty in solving (QCQP). Indeed, in (QCQP-RC), the objective function and all constraints except the $\text{rank}(X) = 1$ are convex in X . Thus, we may consider dropping the trouble-causing rank constraint to obtain the following so-called *semidefinite relaxation* of (QCQP):

$$\begin{aligned} (\text{QCQP-SDR}) : \quad & \text{minimize} \quad A \bullet X \\ & \text{subject to} \quad A_i \bullet X \geq b_i, \\ & \quad \quad \quad X \succeq 0, \\ & \text{where } i = 1, \dots, m. \end{aligned}$$

It is not hard to see that (QCQP-SDR) is an instance of SDP, and hence can be solved efficiently. However, a fundamental issue that one must address is how to convert a globally optimal solution X^* to (QCQP-SDR) into a feasible solution $\tilde{x}$ to (QCQP). Note that if X^* is of rank 1, then there is nothing to do, for we can write $X^* = x^*(x^*)^T$, and x^* will be a feasible (and in fact optimal) solution to (QCQP). On the other hand, if the rank of X^* is larger than 1, then we must somehow extract from it, in an efficient manner, a vector $\tilde{x}$ that is feasible for (QCQP). There are many ways to do this. However, we must emphasize that even though the extracted solution is feasible for (QCQP), it is in general not an optimal solution (for otherwise

we would have solved an NP-hard problem in polynomial time).

We note that the above procedure has been used extensively, for example, in the signal processing community to tackle various communications problems. We refer the interested readers to Refs 9 and 10 for further details and references.

Quality of Semidefinite Relaxations

Given the SDP relaxations of various QCQP problems, it is natural to ask how good those relaxations are. In their seminal work, Goemans and Williamson [6] analyzed an SDP relaxation for the Maximum Cut (MAX-CUT) problem and provided the first provable result concerning the quality of SDP relaxations. Furthermore, it sparked off a great deal of very fruitful research on the quality of various SDP relaxations. Now, let us give an overview of Goemans and Williamson's approach. Such an approach has also been used to establish some of the latter results on the quality of SDP relaxations.

One of the motivations for Goemans and Williamson's work is the MAX-CUT Problem, which is a well-known, NP-hard combinatorial optimization problem and is defined as follows. Suppose that we are given a simple undirected graph $G = (V, E)$ with $V = \{1, \dots, n\}$, and a function $w : E \rightarrow \mathbb{R}_+$ that assigns to each edge $e \in E$ a nonnegative weight w_e . The MAX-CUT problem is that of finding a set $S \subset V$ of vertices such that the total weight of the edges in the cut $(S, V \setminus S)$, that is, sum of the weights of the edges with one end point in S and the other in $V \setminus S$, is maximized. By setting $w_{ij} = 0$ if $(i, j) \notin E$, we may denote the weight of a cut $(S, V \setminus S)$ by

$$w(S, V \setminus S) = \sum_{i \in S, j \in V \setminus S} w_{ij}, \quad (1)$$

and our goal is to choose a set $S \subset V$ such that the quantity in Equation (1) is maximized. The MAX-CUT problem can be formulated as

the following QCQP:

$$\begin{aligned} v^* = \text{maximize} \quad & \frac{1}{2} \sum_{(i,j) \in E} w_{ij}(1 - x_i x_j) \\ \text{subject to} \quad & x_i \in \{-1, 1\} \text{ for } i = 1, \dots, n, \end{aligned} \quad (2)$$

where the variable x_i indicates which side of the cut vertex i belongs to. Specifically, the cut $(S, V \setminus S)$ is given by $S = \{i \in \{1, \dots, n\} : x_i = 1\}$. Note that if vertices i and j belong to the same side of a cut, then $x_i = x_j$, whence its contribution to the objective function in problem (2) is zero. Otherwise, we have $x_i \neq x_j$, whence its contribution to the objective function is $w_{ij}(1 - (-1))/2 = w_{ij}$. Upon applying the techniques described in the section titled “The Basic Technique,” we obtain the following SDP relaxation of problem (2)

$$\begin{aligned} v_{sdp}^* = \text{maximize} \quad & \frac{1}{2} \sum_{(i,j) \in E} w_{ij}(1 - X_{ij}) \\ \text{subject to} \quad & X_{ii} = 1, \\ & X \succeq \mathbf{0}, \\ \text{where } & i = 1, \dots, n. \end{aligned} \quad (3)$$

Note that since problem (3) is a relaxation of problem (2), we have $v_{sdp}^* \geq v^*$.

Now, let X^* be an optimal solution to problem (3). In general, the matrix X^* need not be of the form xx^T , and hence it does not immediately yield a feasible solution to problem (2). However, we can extract from X^* a solution $x' \in \{-1, 1\}^n$ to problem (2) via the following randomized rounding procedure:

1. Compute the *Cholesky factorization* $X^* = U^T U$ of X^* , where $U \in \mathbb{R}^{n \times n}$. Let $u_i \in \mathbb{R}^n$ be the i th column of U . Note that $\|u_i\|_2^2 = 1$ for $i = 1, \dots, n$.
2. Let $r \in \mathbb{R}^n$ be a vector uniformly distributed on the unit sphere $S^{n-1} = \{x \in \mathbb{R}^n : \|x\|_2 = 1\}$.
3. Set $x'_i = \text{sgn}(u_i^T r)$ for $i = 1, \dots, n$, where

$$\text{sgn}(z) = \begin{cases} 1 & \text{if } z \geq 0, \\ -1 & \text{otherwise.} \end{cases}$$

In other words, we choose a random hyperplane through the origin (with r as its normal) and partition the vertices according to whether their corresponding vectors lie “above” or “below” the hyperplane.

It is clear that $x' = (x'_1, \dots, x'_n)$ is a feasible solution to problem (2), and hence we must have

$$v' \equiv \frac{1}{2} \sum_{(i,j) \in E} w_{ij}(1 - x'_i x'_j) \leq v^*.$$

The question now is whether there exists an $\alpha \in (0, 1)$ such that $v' \geq \alpha \cdot v^*$. The factor α is commonly known as the *approximation ratio*. More precisely, since the solution $x' \in \{-1, 1\}^n$ is produced via a randomized procedure, we are interested in its expected objective value, that is,

$$\begin{aligned} \mathbb{E}[v'] &= \frac{1}{2} \mathbb{E} \left[\sum_{(i,j) \in E} w_{ij} (1 - x'_i x'_j) \right] \\ &= \frac{1}{2} \sum_{(i,j) \in E} w_{ij} \mathbb{E} [1 - x'_i x'_j] \\ &= \sum_{(i,j) \in E} w_{ij} \Pr [\text{sgn}(u_i^T r) \neq \text{sgn}(u_j^T r)]. \end{aligned} \quad (4)$$

The following theorem provides a lower bound on $\mathbb{E}[v']$ and allows us to compare it with v_{sdp}^* :

Theorem 1. *Let $u, v \in S^{n-1}$, and let r be a vector uniformly distributed on S^{n-1} . Then, we have*

$$\Pr [\text{sgn}(u^T r) \neq \text{sgn}(v^T r)] = \frac{1}{\pi} \arccos(u^T v).$$

Furthermore, for any $z \in [-1, 1]$, we have

$$\frac{1}{\pi} \arccos(z) \geq \alpha \cdot \frac{1}{2}(1 - z) > 0.878 \cdot \frac{1}{2}(1 - z),$$

where

$$\alpha = \min_{0 \leq \theta \leq \pi} \frac{2\theta}{\pi(1 - \cos \theta)}.$$

Table 1. Quality Analyses of Various SDP Relaxations

Type of Problems	References
Combinatorial optimization	[6, 11–23]
Quadratic optimization	[7, 8, 24–36]
Communications	[37–41]
Geometry	[42–45]

As a corollary to Theorem 1, we have the following:

Corollary 1. *Given an instance (G, w) of the MAX-CUT problem and an optimal solution to problem (3), the randomized rounding procedure above will produce a cut $(S', V \setminus S')$ whose expected objective value satisfies $w(S', V \setminus S') \geq 0.878v^*$.*

Proof. Let x' be the solution obtained from the randomized rounding procedure, and let S' be the corresponding cut. By Equation (4) and Theorem 1, we have

$$\begin{aligned}
\mathbb{E}[w(S', V \setminus S')] &= \frac{1}{\pi} \sum_{(i,j) \in E} w_{ij} \cdot \arccos(u_i^T u_j) \\
&\geq 0.878 \cdot \frac{1}{2} \sum_{(i,j) \in E} w_{ij} (1 - u_i^T u_j) \\
&= 0.878v_{sdp}^* \\
&\geq 0.878v^*,
\end{aligned}$$

as desired.

Note that a crucial step in the above analysis is to study a certain probability question related to the projections of a collection of vectors onto a random vector. This turns out to be a recurring theme in many of the quality analyses of SDP relaxations. Table 1 provides pointers to further theoretical results on the quality of SDP relaxations that arise in various applications.

SEMIDEFINITE RELAXATIONS OF POLYNOMIAL OPTIMIZATION PROBLEMS

A fundamental problem in optimization is that of finding the global minimum of a

real-valued polynomial $p : \mathbb{R}^n \rightarrow \mathbb{R}$ subject to polynomial inequality constraints. Indeed, the class of polynomial functions provides a very powerful modeling tool, and many optimization problems can be formulated as polynomial optimization problems. One example is the MAX-CUT problem in the section titled “Quality of Semidefinite Relaxations,” where the constraint $x_i \in \{-1, 1\}$ can be equivalently formulated as $x_i^2 = 1$. Given its importance, polynomial optimization has been studied intensely in recent years. One approach, which is proposed by Lasserre [46] (see also the excellent survey by Laurent [47]), is to construct a *sequence* of successively tighter SDP relaxations of the given polynomial optimization problem, in such a way that the corresponding optimal values are monotone and converge to the optimal value of the original problem. To fix ideas and simplify notation, let us again focus on the case of *quadratic* optimization problems [48]. To begin, consider the problem

$$\begin{aligned}
(\text{PO}) : \quad v^* &= \text{minimize } g_0(x) \\
&\text{subject to } g_i(x) \geq 0 \\
&\text{for } i = 1, \dots, m,
\end{aligned}$$

where $g_0, g_1, \dots, g_m : \mathbb{R}^n \rightarrow \mathbb{R}$ are quadratic polynomials. Note that we may write the polynomials $g_0, g_1, \dots, g_m$ in *multiindex notation*, namely,

$$g_i(x) = \sum_{\alpha} (g_i)_{\alpha} x^{\alpha} \quad \text{for } i = 0, 1, \dots, m, \quad (5)$$

where $\alpha = (\alpha_1, \dots, \alpha_n) \geq \mathbf{0}$, $x^{\alpha} = x_1^{\alpha_1} \dots x_n^{\alpha_n}$, and $\sum_{i=1}^n \alpha_i \leq 2$. Hence, we may identify the polynomial g_i with its coefficient vector $((g_i)_{\alpha}) \in \mathbb{R}^{(n+1)(n+2)/2}$, where $i = 0, 1, \dots, m$.

Now, observe that each summand in Equation (5) is either a constant or of the form x_i or $x_i x_j$, where $1 \leq i \leq j \leq n$. For terms of the form $x_i x_j$, we may linearize them by introducing the variables y_{ij} . As a result, we have the following *linear programming (LP) relaxation* of (PO):

$$\begin{aligned}
&\text{minimize } \sum_{0 \leq i \leq j \leq n} (g_0)_{ij} y_{ij} \\
&\text{subject to } \sum_{0 \leq i \leq j \leq n} (g_k)_{ij} y_{ij} \geq 0 \quad \text{for } k = 1, \dots, m,
\end{aligned}$$

with $y_{00} = 1$ and $y_{0i} = x_i$ for $i = 1, \dots, n$. To tighten the relaxation, observe that ideally we should have $y_{ij} = y_{0i}y_{0j}$ for $1 \leq i \leq j \leq n$. Hence, we may impose the constraint

$$M_1(\mathbf{y}_1) \equiv \begin{bmatrix} 1 & y_{01} & y_{02} & \cdots & y_{0i} & \cdots & y_{0n} \\ y_{01} & y_{11} & y_{12} & \cdots & y_{1i} & \cdots & y_{1n} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ y_{0j} & y_{1j} & y_{2j} & \cdots & y_{ij} & \cdots & y_{jn} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ y_{0n} & y_{1n} & y_{2n} & \cdots & y_{in} & \cdots & y_{nn} \end{bmatrix} \succeq \mathbf{0},$$

where $\mathbf{y}_1 = (1, y_{01}, \dots, y_{0n}, y_{11}, \dots, y_{nn})$. The first SDP relaxation in the sequence can then be given by

$$\begin{aligned} (\text{PO-SDR1}) : \\ v_1^* &= \inf \sum_{0 \leq i \leq j \leq n} (g_0)_{ij} y_{ij} \\ \text{subject to } &\sum_{0 \leq i \leq j \leq n} (g_k)_{ij} y_{ij} \geq 0, \\ &M_1(\mathbf{y}_1) \succeq \mathbf{0}, \end{aligned}$$

where $k = 1, \dots, m$.

The reader may notice that (PO-SDR1) is simply the standard SDP relaxation of a quadratic optimization problem (see section titled “The Basic Technique”).

To obtain the next SDP relaxation in the sequence, consider a particular constraint

$$\sum_{0 \leq i \leq j \leq n} (g_k)_{ij} y_{ij} \geq 0,$$

where $k = 1, \dots, m$. If we multiply the left-hand side by y_{pq} (where $0 \leq p \leq q \leq n$) and linearize, we obtain

$$g_k y_{pq} = \sum_{0 \leq i \leq j \leq n} (g_k)_{ij} y_{ij} y_{pq}$$

(note that y_{pq} is an entry of $\mathbf{y}_1$). Now, it can be shown [46, 48] that the linear matrix inequality $M_1(g_k \mathbf{y}_1) = [g_k y_{pq}]_{p,q} \succeq \mathbf{0}$ is a valid constraint for the original problem (PO). To further tighten the relaxation, we impose

constraints on the terms y_{ijpq} via

$$\begin{aligned} M_2(\mathbf{y}_2) \\ \equiv \begin{bmatrix} 1 & y_{01} & \cdots & y_{0n} & y_{11} & \cdots & y_{nn} \\ y_{01} & y_{11} & \cdots & y_{1n} & y_{111} & \cdots & y_{1nn} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ y_{0n} & y_{1n} & \cdots & y_{nn} & y_{11n} & \cdots & y_{nnn} \\ y_{11} & y_{111} & \cdots & y_{11n} & y_{1111} & \cdots & y_{11nn} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ y_{nn} & y_{1nn} & \cdots & y_{nnn} & y_{11nn} & \cdots & y_{nnnn} \end{bmatrix} \succeq \mathbf{0}, \end{aligned}$$

where $\mathbf{y}_2 = (1, y_{01}, \dots, y_{nnnn})$. Then, the second SDP relaxation in the sequence is given by

$$\begin{aligned} (\text{PO-SDR2}) : \\ v_2^* &= \inf \sum_{0 \leq i \leq j \leq n} (g_0)_{ij} y_{ij} \\ \text{subject to } &M_1(g_k \mathbf{y}_1) \succeq \mathbf{0}, \\ &M_2(\mathbf{y}_2) \succeq \mathbf{0}, \\ &\text{where } k = 1, \dots, m. \end{aligned}$$

In general, the l th SDP relaxation in the sequence, which is given by

$$\begin{aligned} (\text{PO-SDR})_l : \\ v_l^* &= \inf \sum_{0 \leq i \leq j \leq n} (g_0)_{ij} y_{ij} \\ \text{subject to } &M_{l-1}(g_k \mathbf{y}_{l-1}) \succeq \mathbf{0} \\ &M_l(\mathbf{y}_l) \succeq \mathbf{0}, \\ &\text{for } k = 1, \dots, m, \end{aligned}$$

can be obtained by repeating the above procedure.

The following proposition states that the sequence of optimal values $\{v_l^*\}_l$ is monotone and they all provide lower bounds on the optimal value v^* of the original problem (PO).

Proposition 1. *For $l = 1, 2, \dots$, we have $v_l^* \leq v_{l+1}^* \leq v^*$.*

To prove Proposition 1, it suffices to verify that for $l = 1, 2, \dots$, the feasible region of problem (PO) is contained in that of problem (PO-SDR($l + 1$)), which in turn is contained

in the feasible region of (PO–SDR l). We refer the reader to Refs 46, 48 for details.

Although Proposition 1 implies that a better lower bound on v^* can be obtained by solving a higher order SDP relaxation (PO–SDR l) (where $l = 1, 2, \dots$), it is not clear from Proposition 1 whether the sequence of optimal values $\{v_l^*\}_l$ would converge to v^* . However, if the feasible region of (PO) is compact, then it can be shown that $v_l^* \nearrow v^*$. The proof of such result relies on representation theorems of polynomials that are positive on a compact set (see Ref. 49 for a detailed treatment). We remark that the compactness assumption is not as restrictive as it may seem. It can be guaranteed, for instance, if we know *a priori* that there exists an optimal solution x^* to (PO) with $\|x^*\|_2 \leq r$ for some $r > 0$, since then we can add the redundant polynomial inequality constraint $g_{m+1}(x) = r^2 - \|x\|_2^2 \geq 0$ to (PO) and obtain a compact feasible region. We summarize as follows:

Theorem 2. *Suppose that the feasible region of (PO) is compact. Then, we have $v_l^* \nearrow v^*$.*

There has been much research on the systematic generation of successively tighter SDP relaxations for various polynomial optimization problems. We refer the interested readers to Refs 47, 50–55 and the references therein for further details.

SAFE TRACTABLE APPROXIMATIONS OF CHANCE CONSTRAINED LINEAR MATRIX INEQUALITIES

In many practical applications, the data defining an optimization problem may not be known exactly. This can happen, for example, when we are unable to make precise measurements. Currently, there are several ways to model such data uncertainty. For instance, in the area of robust optimization, the uncertain data are assumed to lie in some bounded set S , and the goal is to find a solution that is feasible for *all* realizations of the uncertain data from the set S . On the other hand, in the

area of chance constrained optimization, the uncertain data are assumed to follow certain probability distribution, and it is assumed that certain constraints can be violated *occasionally*. Thus, the goal here is to find a solution whose constraint violation probability is below a certain threshold. It should be noted that both approaches have their own advantages and disadvantages. In this section, we will focus on the chance constrained optimization approach and see how SDP can be used to tackle a large class of chance constrained optimization problems.

To begin, consider the problem

$$\begin{aligned} & \text{minimize } c^T x \\ (\text{CCP}) : & \text{subject to } \Pr \left(\mathcal{A}_0(x) - \sum_{i=1}^h \xi_i \mathcal{A}_i(x) \geq \mathbf{0} \right) \\ & \geq 1 - \epsilon, (\dagger) \\ & x \in \mathbb{R}^n, \end{aligned}$$

where $c \in \mathbb{R}^n$ is a given objective vector; $\mathcal{A}_0, \mathcal{A}_1, \dots, \mathcal{A}_h : \mathbb{R}^n \rightarrow \mathcal{S}^m$ are affine functions in x with $\mathcal{A}_0(x) \succ \mathbf{0}$ for all $x \in \mathbb{R}^n$; $\xi_1, \dots, \xi_h$ are independent (but not necessarily identical) mean zero random variables; and $\epsilon \in (0, 1)$ is the error tolerance parameter. Problem (CCP) arises from many engineering applications, such as truss topology design and problems in control theory and communications, and has received much attention lately [30, 56–60]. Moreover, it captures chance constrained linear and conic quadratic programming as special cases. In general, the constraint $(\dagger)$ in (CCP) is computationally intractable. In an attempt to circumvent this problem, Ben-Tal and Nemirovski [30, 58] proposed a *safe tractable approximation* of $(\dagger)$ —that is, a system of constraints $\mathcal{H}$ such that (i) x is feasible for $(\dagger)$ whenever it is feasible for $\mathcal{H}$, and (ii) the constraints in $\mathcal{H}$ are efficiently computable. Specifically, their strategy is as follows. First, observe that

$$\begin{aligned} & \Pr \left(\mathcal{A}_0(x) - \sum_{i=1}^h \xi_i \mathcal{A}_i(x) \geq \mathbf{0} \right) \\ & = \Pr \left(\sum_{i=1}^h \xi_i \mathcal{A}_i'(x) \leq I \right), \end{aligned}$$

where $\mathcal{A}'_i(x) = \mathcal{A}_0^{-1/2}(x)\mathcal{A}_i(x)\mathcal{A}_0^{-1/2}(x)$. Now, suppose one can choose $\gamma = \gamma(\epsilon) > 0$ so that whenever

$$\sum_{i=1}^h (\mathcal{A}'_i(x))^2 \preceq \gamma^2 I \quad (6)$$

holds, the constraint $(\dagger)$ is satisfied. Then, the constraint (6) will be a sufficient condition for $(\dagger)$ to hold. The parameter γ can be viewed as the degree of conservatism of the approximation. In particular, a smaller γ results in a larger “gap” between the safe tractable constraint (6) and the original chance constraint $(\dagger)$. Now, the upshot of constraint (6) is that it can be expressed as a linear matrix inequality using the Schur complement:

$$\begin{bmatrix} \gamma \mathcal{A}_0(x) & \mathcal{A}_1(x) & \cdots & \mathcal{A}_h(x) \\ \mathcal{A}_1(x) & \gamma \mathcal{A}_0(x) & & \\ \vdots & & \ddots & \\ \mathcal{A}_h(x) & & & \gamma \mathcal{A}_0(x) \end{bmatrix} \succeq \mathbf{0}. \quad (7)$$

Thus, by replacing $(\dagger)$ with constraint (7), Problem (CCP) becomes tractable. Moreover, any solution $x \in \mathbb{R}^n$ that satisfies constraint (7) will be feasible for the original chance constrained problem (CCP).

Using some deep results from the functional analysis literature, it can be shown that when the random variables $\xi_1, \dots, \xi_h$ are “nice,” there indeed exists a choice of $\gamma > 0$ such that constraint (6) is a sufficient condition for $(\dagger)$ to hold. Specifically, we have the following:

Theorem 3. *Let $\xi_1, \dots, \xi_h$ be independent mean zero random variables, each of which is either (i) supported on $[-1, 1]$, or (ii) normally distributed with unit variance. Consider problem (CCP). Then, for any $\epsilon \in (0, 1/2]$, the positive semidefinite constraint (7) with $\gamma \leq \gamma(\epsilon) \equiv \left(\sqrt{8e \ln(m/\epsilon)}\right)^{-1}$ is a safe tractable approximation of $(\dagger)$.*

The proof of Theorem 3 can be found in Ref. 35; see also Ref. 58.

We refer those readers who are interested in optimization under data uncertainty to the books [61,62] for further techniques and results.

APPLICATIONS IN DATA ANALYSIS

Recently, SDP has been used to tackle various problems in data analysis and machine learning. In this section, we will study one such problem, namely, sparse principal component analysis, and show how it can be tackled using SDP.

Principal component analysis (PCA) [63] is a very important tool in data analysis. It provides a way to reduce the dimension of a given data set, thus revealing the sometimes hidden underlying structure of and facilitating further analysis on the data set. To motivate the problem of finding principal components, consider the following scenario. Suppose that we are interested in some attributes $X_1, \dots, X_n$ of a population. In order to estimate the values of these attributes, one may sample from the population. Specifically, let X_{ij} be the value of the j th attribute of the i th individual, where $i = 1, \dots, m$ and $j = 1, \dots, n$. For $j, k = 1, \dots, n$, define

$$\bar{X}_j = \frac{1}{m} \sum_{i=1}^m X_{ij}, \quad \sigma_{jk} = \frac{1}{m} \sum_{i=1}^m (X_{ij} - \bar{X}_j)(X_{ik} - \bar{X}_k)$$

to be the sample mean of X_j and the sample covariance between X_j and X_k , respectively. Define $\Sigma = [\sigma_{jk}]_{j,k}$ to be the sample covariance matrix. The goal is then to find the *principal components* $u_1, \dots, u_n$ such that the linear combination $\sum_{j=1}^n u_j X_j$ has *maximum* sample variance. In other words, we would like to solve the following problem:

$$\max_{\|u\|_2 \leq 1} u^T \Sigma u, \quad (8)$$

where $u = (u_1, \dots, u_n)$. The model given by problem (8) is based on the belief that principal components with a large associated variance indicate interesting features in the data. However, one of the shortcomings of this model is that the linear combination may use a large number of the original variables, that is, most of the factors $u_1, \dots, u_n$ are *non-zero*, thus posing a difficulty in interpreting which variables are the most influential. This motivates us to consider the problem of finding *sparse* principal components, that is, a set $\{u_1, \dots, u_n\}$ of principal components that

maximizes the variance while at the same time having only a few non-zero u_i 's. There are many ways to formulate such a problem. For instance, one can take the following *penalty function* approach [64]:

$$v(\rho) = \max_{\|u\|_2 \leq 1} \left\{ u^T \Sigma u - \rho \|u\|_0 \right\}, \quad (9)$$

where $\|u\|_0 = |\{i \in \{1, \dots, n\} : u_i \neq 0\}|$ is the number of non-zero elements in the vector $u \in \mathbb{R}^n$, and $\rho \in \mathbb{R}$ is a parameter controlling the level of sparsity. Note that the objective function in problem (9) is nonconvex and the associated optimization problem is hard to solve in general. However, as shown in Ref. 64, it can be relaxed to an SDP. Let us now sketch the main ideas in Ref. 64.

To begin, observe that $\Sigma \succeq \mathbf{0}$, and we may assume without loss that $\Sigma_{11} \geq \Sigma_{22} \geq \dots \geq \Sigma_{nn} \geq 0$. Let $\Sigma^{1/2} \succeq \mathbf{0}$ be such that $\Sigma = \Sigma^{1/2} \Sigma^{1/2}$. It is not hard to show that when $\rho > \Sigma_{11}$, the optimal solution to Equation (9) is given by $u = \mathbf{0}$. Thus, we only need to consider the case where $\rho \leq \Sigma_{11}$. Then, Problem (9) is equivalent to the problem

$$v(\rho) = \max_{\|u\|_2=1} \left\{ u^T \Sigma u - \rho \|u\|_0 \right\}. \quad (10)$$

For a given vector $u \in \mathbb{R}^n$, let $w(u) \in \{0, 1\}^n$ be the indicator vector of the *sparsity pattern* of u , that is, $w(u)_i = 1$ iff $u_i \neq 0$ for $i = 1, \dots, n$. Observe that

$$u^T \Sigma u = \bar{u}^T \left(\text{diag}(w(u)) \Sigma \text{diag}(w(u)) \right) \bar{u}$$

for any $\bar{u} \in \mathbb{R}^n$ such that $\bar{u}_i = u_i$ whenever $u_i \neq 0$, where $i = 1, \dots, n$. On the other hand, by the Courant–Fischer characterization, for a given sparsity pattern vector $w \in \{0, 1\}^n$, we have

$$\begin{aligned} \max_{\|u\|_2=1} u^T \left(\text{diag}(w) \Sigma \text{diag}(w) \right) u \\ = \lambda_{\max} \left(\text{diag}(w) \Sigma \text{diag}(w) \right), \end{aligned}$$

where $\lambda_{\max}(M)$ is the largest eigenvalue of the matrix M . Thus, upon letting $\sigma_i \in \mathbb{R}^n$ to be the i th column of $\Sigma^{1/2}$ (where $i = 1, \dots, n$),

we may write problem (10) as

$$\begin{aligned} v(\rho) &= \max_{w \in \{0,1\}^n} \left\{ \lambda_{\max} \left(\text{diag}(w) \Sigma \text{diag}(w) \right) - \rho e^T w \right\} \\ &= \max_{w \in \{0,1\}^n} \left\{ \lambda_{\max} \left(\text{diag}(w) \Sigma^{1/2} \Sigma^{1/2} \text{diag}(w) \right) \right. \\ &\quad \left. - \rho e^T w \right\} \\ &= \max_{w \in \{0,1\}^n} \left\{ \lambda_{\max} \left(\Sigma^{1/2} \text{diag}(w) \Sigma^{1/2} \right) - \rho e^T w \right\} \end{aligned} \quad (11)$$

$$\begin{aligned} &= \max_{\|u\|_2=1} \max_{w \in \{0,1\}^n} \left\{ u^T \left(\Sigma^{1/2} \text{diag}(w) \Sigma^{1/2} \right) u \right. \\ &\quad \left. - \rho e^T w \right\} \end{aligned}$$

$$= \max_{\|u\|_2=1} \max_{w \in \{0,1\}^n} \sum_{i=1}^n w_i \left[\left(\sigma_i^T u \right)^2 - \rho \right] \quad (12)$$

$$= \max_{\|u\|_2=1} \sum_{i=1}^n \left[\left(\sigma_i^T u \right)^2 - \rho \right]_+, \quad (13)$$

where Equation (11) follows from the fact that $\lambda_{\max}(M^T M) = \lambda_{\max}(M M^T)$ for any matrix M and $\text{diag}(w)^2 = \text{diag}(w)$ for any $w \in \{0, 1\}^n$, and Equation (12) follows from the fact that

$$\begin{aligned} u^T \left(\Sigma^{1/2} \text{diag}(w) \Sigma^{1/2} \right) u &= \left\| \text{diag}(w) \Sigma^{1/2} u \right\|_2^2 \\ &= \sum_{i=1}^n w_i^2 \left(\sigma_i^T u \right)^2 \\ &= \sum_{i=1}^n w_i \left(\sigma_i^T u \right)^2. \end{aligned}$$

Note that the objective function in problem (13) is still nonconvex. However, the upshot of problem (13) is that the objective function is linear in $u_i u_j$, where $i, j = 1, \dots, n$. In particular, let $U = u u^T \in \mathbb{R}^{n \times n}$. Then, it is easy to verify that $(\sigma_i^T u)^2 = \sigma_i^T U \sigma_i$ for $i = 1, \dots, n$. Moreover, for a symmetric matrix U , we have $U = u u^T$ and $\|u\|_2 = 1$ iff $\text{tr}(U) = 1$, $\text{rank}(U) = 1$ and $U \succeq \mathbf{0}$. Thus, we see that problem (13) is equivalent to the following problem:

$$\begin{aligned} v(\rho) &= \text{maximize} \quad \sum_{i=1}^n \left(\sigma_i^T U \sigma_i - \rho \right)_+ \\ &\text{subject to} \quad \text{tr}(U) = 1, \\ &\quad U \succeq \mathbf{0}, \text{rank}(U) = 1. \end{aligned} \quad (14)$$

It is not hard to see that the function $U \mapsto \sum_{i=1}^n (\sigma_i^T U \sigma_i - \rho)_+$ is *convex*. Unfortunately, Problem (14) is still hard to solve in general, since we are maximizing a convex function, and the constraint $\text{rank}(U) = 1$ is not convex. However, not all is lost, as we may proceed as follows. First, let us introduce a notation. Given an $n \times n$ symmetric matrix M , let $\lambda_1, \dots, \lambda_n$ be its eigenvalues. Define

$$\text{tr}(M)_+ = \sum_{i=1}^n \max\{\lambda_i, 0\}.$$

Now, observe that if $U = uu^T$ and $\|u\|_2 = 1$, then $U^{1/2} = U = uu^T$. Moreover, for any $\alpha \in \mathbb{R}$, the matrix αuu^T has one eigenvalue equal to α and $n - 1$ eigenvalues equal to 0, which implies that $\text{tr}(\alpha uu^T)_+ = \alpha_+$. It follows that

$$\begin{aligned} (\sigma_i^T U \sigma_i - \rho)_+ &= \text{tr}((\sigma_i^T uu^T \sigma_i - \rho) uu^T)_+ \\ &= \text{tr}(u(u^T \sigma_i \sigma_i^T u - \rho)u^T)_+ \\ &= \text{tr}(U^{1/2} \sigma_i \sigma_i^T U^{1/2} - \rho U)_+. \end{aligned}$$

The point of the above manipulation is that the function $U \mapsto \text{tr}(U^{1/2} \sigma_i \sigma_i^T U^{1/2} - \rho U)_+$ is *concave*. Specifically, one can prove the following:

Theorem 4. *Let $M \in \mathbb{S}^n$ and $X \in \mathbb{S}_+^n$. Then, we have*

$$\begin{aligned} \text{tr}(X^{1/2} M X^{1/2})_+ &= \max_{X \succeq P \succeq 0} \text{tr}(PM) \\ &= \min_{Y \succeq M, Y \succeq 0} \text{tr}(YX). \end{aligned} \quad (15)$$

In particular, the function $X \mapsto \text{tr}(X^{1/2} M X^{1/2})_+$ is concave on $\mathbb{S}_+^n$.

Upon applying Theorem 4 and dropping the problematic rank constraint $\text{rank}(U) = 1$ in problem (14), we obtain the following *convex relaxation*:

$$\begin{aligned} v'(\rho) &= \text{maximize} \quad \sum_{i=1}^n \text{tr}(U^{1/2} \sigma_i \sigma_i^T U^{1/2} - \rho U)_+ \\ &\text{subject to} \quad \text{tr}(U) = 1, \\ &\quad U \succeq 0. \end{aligned} \quad (16)$$

Upon letting $M_i(\rho) = \sigma_i \sigma_i^T - \rho I$ for $i = 1, \dots, n$ and using Equation (15), we see that problem (16) is equivalent to

$$\begin{aligned} v'(\rho) &= \text{maximize} \quad \sum_{i=1}^n \text{tr}(P_i M_i(\rho)) \\ &\text{subject to} \quad \text{tr}(U) = 1, \\ &\quad U \succeq P_i \succeq 0 \\ &\quad U \succeq 0, \\ &\quad \text{for } i = 1, \dots, n, \end{aligned}$$

which is an SDP.

It turns out that SDP is a very powerful tool for addressing a host of data analysis and machine learning problems. We refer interested readers to Refs 65–70 for further details.

Birmingham, UK

In this article we consider a *semi-infinite programming* (SIP) problem of the form

SIP: minimize $f(x)$ subject to $x \in M$, (1)
where the *feasible set* M is given as

$$M = \{x \in \mathbb{R}^n \mid G(x, y) \geq 0, y \in Y\}$$

and the *index set* Y is defined as

$$Y = \{y \in \mathbb{R}^r \mid u_l(y) = 0, l \in A, v_k(y) \leq 0, k \in B\}.$$

Assume that:

- The functions $f, G, u_l, l \in A = \{1, \dots, a\}$, $v_k, k \in B = \{1, \dots, b\}$ are real-valued and sufficiently smooth (i.e., they are once (twice) continuously differentiable when considering their first (second) derivatives).
- The index set $Y \subset \mathbb{R}^r$ is compact and, in general, infinite. Each element $\bar{y} \in Y$ represents a corresponding inequality constraint $G(\cdot, \bar{y}) \geq 0$. Obviously, the set Y is defined by finitely many equality and inequality constraints and, therefore, it has the structure of the feasible set of a finite programming problem.

Since there are finitely many decision variables $x = (x_1, \dots, x_n)$ and infinitely many constraints $G(x, \bar{y}) \geq 0$, $\bar{y} \in Y$, the problem is called *semi-infinite*. The objective of a solution method for SIP is to find a *local*

minimizer, that is, a *feasible point* $\bar{x} \in M$ satisfying

$$f(\bar{x}) \leq f(x) \quad (2)$$

for all feasible points x from a certain neighborhood of $\bar{x}$. Under certain assumptions, one is interested in calculating a *global minimizer* of SIP, that is, a point $\bar{x} \in M$ satisfying Equation (2) for all $x \in M$.

SIP has a wide range of applications and it became a vivid research area within mathematical programming over the last two decades; for more details we refer to the survey papers [1,2], the monographs [3–5], and the books [6,7], which contain state-of-the-art articles on theory, solution methods, and applications of SIP.

When the SIP model is applied to real-life problems, the index set Y may refer, for example

- to a (compact) time interval: at each time point of this interval a corresponding velocity is restricted (e.g., control problems in robotics);
- or to a geographic area: at each point of this area the level of allowed contamination is restricted (e.g., control problems in chemical engineering).

SIP originated partially from approximation problems: the problem of Chebyshev approximation is to approximate a continuous function $v: \mathbb{R}^r \rightarrow \mathbb{R}$ uniformly on a compact set $Y \subset \mathbb{R}^r$ by means of an n -parameter family of functions $V(x, \cdot)$ (e.g., a family of particular polynomials whose coefficients (parameters) are $x = (x_1, \dots, x_n)$).

This approximation problem reads as follows:

$$\text{minimize } p(x) := \max_{y \in Y} |v(y) - V(x, y)|$$

and it can be rewritten as the particular SIP problem (with $x_{n+1} \in \mathbb{R}$)

$$\begin{aligned} & \underset{x \in \mathbb{R}^n}{\text{minimize}} \{x_{n+1} \mid -x_{n+1} \leq v(y) \\ & \quad -V(x, y) \leq x_{n+1}, y \in Y\}. \end{aligned}$$

Compared to this special structure of an approximation problem, the more general setting (Eq. 1) allows taking into account any set of constraints of the form $G(x, y) \geq 0$, $y \in Y$.

In some applications, the feasible set contains additionally finitely many equality constraints $h_i(x) = 0$, $i \in I = \{1, \dots, m\}$ ($m < n$), where the gradients of these constraints are linearly independent at all feasible points.

The latter property means that these constraints describe locally around the feasible set an $(n - m)$ -dimensional manifold and, therefore, all the results presented in the following can be applied to this case as well. Therefore, in order to avoid unnecessary technicalities, we restrict ourselves throughout this article to the case $I = \emptyset$.

This article is organized as follows. In the section titled “First Order Optimality Conditions,” we discuss constraint qualifications, first order optimality conditions and, in particular, linear SIP problems. In the section titled “The Reduction Approach” we present the reduction approach, which allows the local transformation of an SIP problem into a finite programming problem. The next section refers to “Second Order Optimality Conditions,” and the section titled “Structural stability of SIP” considers several stability concepts including strong stability of a stationary point and structural stability of the SIP problem. Finally, in the section titled “Final Remarks,” we refer briefly to solution methods and generalized SIP problems.

Now, we introduce some notations used later:

- $C^k(U, \mathbb{R})$, $k \geq 1$ denotes the space of k -times continuously differentiable real-valued functions defined on $U \subset \mathbb{R}^n$.
- $C^{1,1}(U, \mathbb{R})$ denotes the space of continuously differentiable real-valued functions defined on $U \subset \mathbb{R}^n$ with Lipschitz continuous gradient.

- If $g \in C^1(U, \mathbb{R})$, then the row vector $Dg(x)$ ($D_{x^1}g(x)$) denotes the derivative (partial derivative with respect to the subvector x^1 of x) of g at x . Second derivatives are analogously represented.
- The space $C^k(\mathbb{R}^n, \mathbb{R})$, $k \geq 1$ can be topologized by means of the *strong* or *Whitney C^k -topology*, which is generated by allowing perturbations of the function and their derivatives up to order k and whose set of neighborhoods is controlled by means of continuous positive functions $\varepsilon(\cdot) : \mathbb{R}^n \rightarrow \mathbb{R}$. This topology is denoted by C_s^k [8,9].

FIRST ORDER OPTIMALITY CONDITIONS

Throughout this article assume that the *linear independence constraint qualification* LICQ holds at each $\bar{y} \in Y$, that is, the gradients

$$\begin{aligned} & Du_l(\bar{y}), l \in A, Dv_k(\bar{y}), k \in B_0(\bar{y}) \\ & = \{k \in B \mid v_k(\bar{y}) = 0\} \end{aligned}$$

are linearly independent. Jongen *et al.* [9] have shown that LICQ at all $y \in Y$ is a generic property with respect to the C_s^1 -topology for the defining functions $u_l, l \in A, v_k, k \in B$. Furthermore, this property implies that for each $\bar{y} \in Y$ there exist neighborhoods U of $\bar{y}$ and W of the origin 0_r of $\mathbb{R}^r$ as well as a diffeomorphism $\psi : \mathbb{R}^r \rightarrow \mathbb{R}^r$ such that $\psi(\bar{y}) = 0_r$ and

$$\psi[Y \cap U] = (0_a \times \mathbb{H}^{|B_0(\bar{y})|} \times \mathbb{R}^{r-a-|B_0(\bar{y})|}) \cap W,$$

where $\mathbb{H}^t = \{z \in \mathbb{R}^t \mid z_i \geq 0, i = 1, \dots, t\}$ [9].

As for a finite programming problem, the set of active constraints at a feasible point is important for optimality conditions. We define for $\bar{x} \in M$ the set

$$Y_0(\bar{x}) = \{y \in Y \mid G(\bar{x}, y) = 0\}.$$

A significant difference between finite and semi-infinite programming problems is illustrated in the following example.

Example 1. Consider first the set Y as the feasible set of a finite programming problem. Obviously, for each $\bar{y} \in Y$ there exists a neighborhood U of $\bar{y}$ such that

$$B_0(y) \subseteq B_0(\bar{y}) \text{ for all } y \in Y \cap U, \quad (3)$$

that is, the set of active constraints at $y \in Y \cap U$ is a subset of the set of active constraints at $\bar{y}$. This property is important for many solution methods in finite programming. On the other hand, consider now the sphere $S^{n-1} \subset \mathbb{R}^n$, which has a nonempty (and infinite) boundary ∂S^{n-1} . At each of its boundary points the corresponding tangent space forms the zero-set of a linear inequality. Then S^{n-1} is described by these infinitely many linear inequality constraints (intersection of infinitely many half-spaces) and at each boundary point $\bar{x} \in \partial S^{n-1}$ there exists exactly one active constraint ($|Y_0(\bar{x})| = 1$). In particular, for any two different points $x^1, x^2 \in S^{n-1}$ we have $Y_0(x^1) \cap Y_0(x^2) = \emptyset$ and, therefore, a relationship analogous to Equation (3) is not fulfilled for SIP problems in general (obviously, S^{n-1} can be substituted by other convex sets). The control of the set of active constraints is one of the main features in SIP.

In the remainder of this article let $\bar{x} \in M$ be our point under consideration. The following simple observation will play a crucial role. Obviously, each active index $\bar{y} \in Y_0(\bar{x})$ is a *global minimizer* of the (parametric) finite programming problem

$$L(\bar{x}) : \text{minimize } G(\bar{x}, y) \text{ subject to } y \in Y.$$

This problem depends on the n -dimensional parameter $\bar{x}$ and it is called *lower level problem*. Hence, finding one (or all) active constraint(s) at $\bar{x}$ means finding one (or all) global minimizers of the corresponding lower level problem $L(\bar{x})$. In the general nonconvex case this is not possible by using deterministic methods. Now, let $\bar{y} \in Y_0(\bar{x})$. By LICQ and the well-known Karush-Kuhn-Tucker (KKT) optimality conditions for finite programming [10], there exist uniquely determined multipliers $\bar{\alpha}_l, l \in A, \bar{\beta}_k \geq 0, k \in B_0(\bar{y})$ such that

$$D_y G(\bar{x}, \bar{y}) + \sum_{l \in A} \bar{\alpha}_l D u_l(\bar{y}) + \sum_{k \in B_0(\bar{y})} \bar{\beta}_k D v_k(\bar{y}) = 0. \quad (4)$$

Furthermore, we define the set

$$\Sigma = \{x \in M \mid x \text{ is a local minimizer of SIP}\}.$$

The following theorem presents several (dual) first order optimality conditions for SIP [1,11].

Theorem 1. *First order necessary optimality condition:*

(i) *Let $\bar{x} \in \Sigma$. Then, the system*

$$Df(\bar{x})\xi < 0, D_x G(\bar{x}, y)\xi > 0, \forall y \in Y_0(\bar{x})$$

has no solution $\xi \in \mathbb{R}^n$.

(ii) *First order necessary optimality condition of Fritz John type:*

Let $\bar{x} \in \Sigma$. Then, there exist finitely many $y^j \in Y_0(\bar{x}), j = 1, \dots, q$ and $\mu_j \geq 0, j = 0, \dots, q, \sum_{j=0}^q \mu_j > 0$ ($q = 0$ is possible) such that

$$\mu_0 Df(\bar{x}) - \sum_{j=1}^q \mu_j D_x G(\bar{x}, y^j) = 0. \quad (5)$$

(iii) *First order sufficient optimality condition:*

Assume that the system

$$Df(\bar{x})\xi \leq 0, D_x G(\bar{x}, y)\xi \geq 0, \forall y \in Y_0(\bar{x})$$

has only the trivial solution $\xi = 0$. Then, $\bar{x} \in \Sigma$ and there exists a neighborhood $U \subset \mathbb{R}^n$ of $\bar{x}$ such that $f(\bar{x}) < f(x)$ for all $x \in M \cap U \setminus \{\bar{x}\}$.

In the sequel, we will use the following two constraint qualifications (which are called extended since they are extensions of the corresponding well-known constraint qualifications in finite programming).

The extended linear independence constraint qualification (ELICQ) holds at $\bar{x}$ if the vectors $D_x G(\bar{x}, y), y \in Y_0(\bar{x})$ are linearly independent.

The *extended Mangasarian Fromovitz constraint qualification* (EMFCQ) holds at $\bar{x} \in M$ if there exists a vector $\xi \in \mathbb{R}^n$ such that $D_x G(\bar{x}, y) \xi > 0$ for all $y \in Y_0(\bar{x})$.

Obviously, if ELICQ holds at $\bar{x}$, then EMFCQ holds at $\bar{x}$ as well. Furthermore, if EMFCQ holds at $\bar{x} \in \Sigma$, then we have $\mu_0 \neq 0$ in Equation (5) and we get

First order necessary optimality condition of Karush-Kuhn-Tucker type [1,11]:

Let $\bar{x} \in \Sigma$ and assume that EMFCQ holds at $\bar{x}$. Then, there exist $y^j \in Y_0(\bar{x})$, $j = 1, \dots, q$ and $\mu_j \geq 0$, $j = 1, \dots, q$ such that the gradients $D_x G(\bar{x}, y^j)$, $j = 1, \dots, q$ ($q = 0$ is possible) are linearly independent and

$$Df(\bar{x}) - \sum_{j=1}^q \mu_j D_x G(\bar{x}, y^j) = 0. \quad (6)$$

Analogously to finite programming we call a feasible point $\bar{x} \in M$ that fulfills Equation (6) a *stationary point of SIP*. A stationary point can be a local minimizer, a saddle point, or a local maximizer of SIP. In the case of a convex SIP problem (where the functions $f(\cdot)$ and $-G(\cdot, y)$, $y \in Y$ are convex) each stationary point is also a global minimizer of SIP.

Finally in this section, we will consider the particular case of a linear SIP problem, which is defined as follows:

LSIP: minimize $c^\top x$ subject to $x \in M_L$,

where the feasible set is

$$M_L = \{x \in \mathbb{R}^n \mid d(y)^\top x - e(y) \geq 0, y \in Y\}$$

with $c \in \mathbb{R}^n$ and $d: Y \rightarrow \mathbb{R}^n$, $e: Y \rightarrow \mathbb{R}$ are continuous functions and Y is defined as above. Obviously, M_L is a convex set (intersection of half-spaces). The *Slater condition* holds at M_L if there exists an $x^0 \in M_L$ such that $a(y)^\top x^0 - b(y) > 0$ for all $y \in Y$. As in finite programming, the Slater condition holds at M_L if and only if EMFCQ holds at all $x \in M_L$. Applying the above presented first order condition to LSIP we obtain

First order sufficient optimality condition for LSIP:

Let $\bar{x} \in M_L$ and $y^j \in Y_0(\bar{x})$, $j = 1, \dots, q$. Assume that there exist $\mu_j > 0$, $j = 1, \dots, q$ such that

$$c - \sum_{j=1}^q \mu_j a(y^j) = 0. \quad (7)$$

Then, $\bar{x}$ is a global minimizer of LSIP.

If, additionally, the Slater condition holds at M_L , then Equation (7) is also a necessary optimality condition.

Sometimes, solution methods for SIP use at certain iteration points particular auxiliary LSIP problems. The problem

LSIP $^{\bar{x}}$: minimize $f^{\bar{x}}(x)$ subject to $M^{\bar{x}}$

is called the *linearized problem at $\bar{x}$* where

$$f^{\bar{x}}(x) = f(\bar{x}) + Df(\bar{x})(x - \bar{x}),$$

$$M^{\bar{x}} = \{x \in \mathbb{R}^n \mid G^{\bar{x}}(x, y) \geq 0, y \in Y\}, \text{ and}$$

$$G^{\bar{x}}(x, y) = G(\bar{x}, y) + D_x G(\bar{x}, y)(x - \bar{x}), y \in Y.$$

A simple iteration procedure is to take the solution of LSIP $^{x^i}$ as the next iteration point x^{i+1} . We conclude this section by providing some relationship between the original problem SIP and a related linearized problem LSIP $^{\bar{x}}$.

Proposition 1 [1,11].

- (i) If EMFCQ holds at $\bar{x}$, then the Slater condition holds at $M^{\bar{x}}$.
- (ii) If EMFCQ holds at $\bar{x}$ and $\bar{x} \in \Sigma$, then $\bar{x}$ is a local minimizer of LSIP $^{\bar{x}}$.
- (iii) If $\tilde{x}$ is a local minimizer of LSIP $^{\bar{x}}$ and $\bar{x}$ is not a local minimizer of LSIP $^{\bar{x}}$, then we have

$$Df(\bar{x})(\tilde{x} - \bar{x}) < 0, D_x G(\bar{x}, y)(\tilde{x} - \bar{x}) \geq 0, \\ \forall y \in Y_0(\bar{x}).$$

For more details on linear SIP, we refer to Goberna and López [3].

THE REDUCTION APPROACH

One of the main challenges in SIP is the handling of the *infinite* index set Y . In this section we consider properties under which the feasible set M can be described locally around $\bar{x}$ by *finitely* many continuously differentiable inequality constraints.

Let $\bar{y} \in Y_0(\bar{x})$ and the uniquely determined multipliers $\bar{\alpha}_l$, $l \in A$, $\bar{\beta}_k \geq 0$, $k \in B_0(\bar{y})$ be given as in Equation (4). Define $B_+(\bar{y}) = \{k \in B \mid \bar{\beta}_k > 0\}$. The so-called *strong second order sufficient condition* SSOSC [12] holds at $\bar{y}$ if the matrix $Q^\top P Q$ is positive definite where

$$P = D_{yy}^2 G(\bar{x}, \bar{y}) + \sum_{l \in A} \bar{\alpha}_l D^2 u_l(\bar{y}) + \sum_{k \in B_0(\bar{y})} \bar{\beta}_k D^2 v_k(\bar{y})$$

and Q is an $(r, r - a - |B_+(\bar{y})|)$ —matrix whose columns form a basis of the tangent space

$$\{y \in \mathbb{R}^r \mid Du_l(\bar{y})y = 0, l \in A, Dv_k(\bar{y})y = 0, k \in B_+(\bar{y})\}.$$

If SSOSC holds at $\bar{y}$, then $\bar{y}$ is called a *strongly stable local minimizer* of $L(\bar{x})$ (see Kojima [13] for more details on strong stability) and we get the following statement.

Theorem 2 [13]. *Let $\bar{y} \in Y_0(\bar{x})$ be chosen as above and assume that SSOSC holds at $\bar{y}$. Then there exist an open neighborhood U of $\bar{x}$ and a uniquely determined (implicit) function*

$$\hat{y} : x \in U \mapsto \hat{y}(x) \in \mathbb{R}^r$$

with the following properties:

- (a) $\hat{y}(\bar{x}) = \bar{y}$.
- (b) $\hat{y}(x)$ is a local minimizer of $L(x)$ and SSOSC holds at $\hat{y}(x)$ for all $x \in U$.
- (c) $\hat{y}$ is a Lipschitz continuous function and $G(\cdot, \hat{y}(\cdot)) \in C^{1,1}(U, \mathbb{R})$.
- (d) If $B_+(\bar{y}) = B_0(\bar{y})$, then $\hat{y}$ is a continuously differentiable function and $G(\cdot, \hat{y}(\cdot)) \in C^2(U, \mathbb{R})$.

If $B_+(\bar{y}) = B_0(\bar{y})$ and SSOSC holds at $\bar{y} \in Y_0(\bar{x})$, then $\bar{y}$ is called a *nondegenerate* minimizer of $L(\bar{x})$. Under this latter condition, the proposition (d) in Theorem 2 is a straightforward consequence of the implicit function theorem because of the nonsingularity of the Jacobian of the system

$$\begin{aligned} G(x, y) + \sum_{l \in A} \alpha_l u_l(y) + \sum_{k \in B_+(\bar{y})} \beta_k v_k(y) &= 0 \\ u_l(y) &= 0, l \in A \\ v_k(y) &= 0, k \in B_+(\bar{y}). \end{aligned}$$

Now, we recall the so-called *reduction approach* [14–16] under which the feasible set M can be described locally around $\bar{x}$ by finitely many $C^{1,1}$ – or C^2 – constraints. The *reduction approach* RA holds at $\bar{x} \in M$ if SSOSC holds at y for all $y \in Y_0(\bar{x})$.

Theorem 3. *Assume that RA holds at $\bar{x} \in M$. Then we have:*

- (a) $Y_0(\bar{x})$ is a finite set, say $Y_0(\bar{x}) = \{y^1, \dots, y^q\}$ (Note that Y is compact).
- (b) There exists an open neighborhood U of $\bar{x}$ and uniquely determined Lipschitz continuous (implicit) functions

$$\hat{y}^j : x \in U \mapsto \hat{y}^j(x) \in \mathbb{R}^r, j = 1, \dots, q,$$

which are defined analogously to $\hat{y}$ in Theorem 2 (i.e., $\hat{y}^j(\bar{x}) = y^j$, $j = 1, \dots, q, \dots$). In particular, we have

$$G(\cdot, \hat{y}^j(\cdot)) \in C^{1,1}(U, \mathbb{R}), j = 1, \dots, q.$$

- (c) Locally around $\bar{x}$ the feasible set M is described as

$$M \cap U = \left\{ x \in U \mid G(x, \hat{y}^j(x)) \geq 0, j = 1, \dots, q \right\}.$$

Although the functions $\hat{y}^j$, $j = 1, \dots, q$ in the latter theorem are only implicitly known, the derivatives of the constraints $G(x, \hat{y}^j(x))$ can be calculated explicitly (which is important for numerical methods using first order conditions):

$$\begin{aligned} DG(x, \hat{y}^j(x)) &= D_x G(x, y) \\ &+ D_y G(x, y) D\hat{y}^j(x) \Big|_{y=\hat{y}^j(x)} = D_x G(x, y), \end{aligned}$$

where the latter equation is a consequence of the fact that $\hat{y}^j(x)$ is a local minimizer of $L(x)$. Finally, we mention that the reduction approach is a generic property [5].

SECOND ORDER OPTIMALITY CONDITIONS

In this section we present a second order optimality condition for $\bar{x} \in \Sigma$ under the assumption that RA holds at $\bar{x}$ (see Hettich and Still [17] for more details). We also refer to Rückmann [18] where second order optimality conditions are presented for the more complicated case that RA does not hold at $\bar{x}$ and, in particular, where $Y_0(\bar{x})$ can be an infinite set.

In the remainder of this section assume that $\bar{x}$ is a stationary point of SIP and that RA holds at $\bar{x}$. We will use the terminology as introduced in Theorem 3. If EMFCQ holds at $\bar{x}$, then there exist multipliers $\lambda_j \geq 0, j = 1, \dots, q$ such that

$$Df(\bar{x}) - \sum_{j=1}^q \lambda_j D_x G(\bar{x}, \hat{y}^j(\bar{x})) = 0, \lambda \geq 0, \quad (8)$$

and, by Gauvin [19], the set

$$\Lambda = \{\lambda \in \mathbb{R}^q \mid \lambda \text{ is a solution of (8)}\}$$

is nonempty and compact.

Now consider for each $y^j, j = 1, \dots, q$ the following auxiliary lower level problem

$$L^j(\bar{x}) : \text{minimize } G(\bar{x}, y) \text{ subject to } y \in Y^j,$$

where

$$\begin{aligned} Y^j &= \{y \in \mathbb{R}^r \mid u_l(y) = 0, l \in A, \\ &\quad v_k(y) = 0, k \in B_0(\bar{y}), \\ &\quad v_\rho(y) \geq 0, \rho \in B \setminus B_0(\bar{y})\}. \end{aligned}$$

Since RA holds at $\bar{x}$ the property SSOSC holds at the global minimizer y^j of $L^j(\bar{x}), j = 1, \dots, q$. By Theorem 2, there exist uniquely determined implicit functions $\hat{y}_0^j, j = 1, \dots, q$, defined on a neighborhood U_0 of $\bar{x}$ with analogous properties ($\hat{y}_0^j(\bar{x}) = y^j, j = 1, \dots, q, \dots$). Now, we can state the following result.

Theorem 4 [18,20]. *Second order sufficient optimality condition:*

Assume that $\bar{x}$ is a stationary point of SIP and that RA and EMFCQ hold at $\bar{x}$. If for each $\lambda \in \Lambda$ the matrix

$$D^2f(\bar{x}) - \sum_{j=1}^q \lambda_j D^2G(\bar{x}, \hat{y}_0^j(\bar{x}))$$

is positive definite on the tangent space

$$\begin{aligned} T(\lambda) &= \{w \in \mathbb{R}^n \mid D_x G(\bar{x}, y^j)w = 0, \\ &\quad j \in \{v \in \{1, \dots, q\} \mid \lambda_v > 0\}\}, \end{aligned}$$

then $\bar{x} \in \Sigma$ and there exists a neighborhood U of $\bar{x}$ such that $f(\bar{x}) < f(x)$ for all $x \in M \cap U \setminus \{\bar{x}\}$.

We also refer to Bonnans and Shapiro [21] and Klatte and Kummer [22] for more details on second order optimality conditions.

STRUCTURAL STABILITY OF SIP

Stability properties play an important role for SIP problems with noise or perturbed data. In this section we briefly describe the concept of structural stability of an SIP problem that, in particular, includes the (topological) stability of the feasible set M and the strong stability of stationary points (see Jongen and Rückmann [23] for more details). We start with an observation on the structure of the feasible set.

Theorem 5. *Structure of the feasible set M [24]:*

- (a) *Assume that RA holds at $\bar{x} \in M$ (and apply the terminology used in Theorem 3). If ELICQ holds at $\bar{x}$, then the functions $G(\cdot, y^j(\cdot)), j = 1, \dots, q$ can be used as a new local $C^{1,1}$ -coordinate system around $\bar{x}$. Hence, there exist neighborhoods U of $\bar{x}$ and W of the origin $0_n \in \mathbb{R}^n$ and a diffeomorphism $\phi^1 : \mathbb{R}^n \rightarrow \mathbb{R}^n$ such that $\phi^1(\bar{x}) = 0_n$ and*

$$\phi^1[M \cap U] = (\mathbb{H}^q \times \mathbb{R}^{n-q}) \cap W$$

(see also the analogous consideration for $\bar{y} \in Y$ in the section titled “First Order Optimality Conditions”).

- (b) If EMFCQ holds at $\bar{x} \in M$ and $Y_0(\bar{x}) \neq \emptyset$, then there exist neighborhoods U of $\bar{x}$ and W of 0_n and a homeomorphism $\phi^2 : \mathbb{R}^n \rightarrow \mathbb{R}^n$ such that $\phi^2(\bar{x}) = 0_n$ and

$$\phi^2[M \cap U] = (\mathbb{H}^1 \times \mathbb{R}^{n-1}) \cap W.$$

- (c) If EMFCQ holds at all $x \in M$, then M is a Lipschitzian manifold with boundary of dimension n , where the boundary ∂M is equal to

$$\left\{ x \in \mathbb{R}^n \mid \min_{y \in Y} G(x, y) = 0 \right\}.$$

The proposition (c) in the latter theorem is obviously a generalization of the local statement in (b) to the whole set M .

The property that EMFCQ holds at all $x \in M$ is a generic property with respect to the C_s^1 -topology for the function G [24]. The following theorem shows that EMFCQ plays an important role for the topological stability of M . The feasible set M is called *topologically stable* if there exists a C_s^1 -neighborhood $F \subset C^1(\mathbb{R}^n \times \mathbb{R}^r, \mathbb{R})$ of G such that for each $\tilde{G} \in F$ the corresponding feasible set $\{x \in \mathbb{R}^n \mid \tilde{G}(x, y) \geq 0, y \in Y\}$ is homeomorphic with M .

Theorem 6. *Topological stability of the feasible set M [24]:*

- (a) If EMFCQ holds at all $x \in M$, then M is topologically stable.
 (b) If M is compact and topologically stable, then EMFCQ holds at all $x \in M$.

Next, we refer to the *strong stability of a stationary point*. This concept was introduced by Kojima [13] for finite programming problems and it refers to the existence, local uniqueness, and continuous dependence on local C^2 -perturbations of the defining functions (i.e., (f, G)) when considering a stationary point of SIP; however, we used this concept already in the context of Theorem 2). Kojima

[13] provided an algebraic characterization of the strong stability of a stationary point of a finite programming problem by using the first and second derivatives of the defining functions. Then, the concept of strong stability was extended to SIP problems and in Rückmann [18] an algebraic characterization was presented for the following three cases of a stationary point $\bar{x}$ of SIP:

- ELICQ and RA hold at $\bar{x}$,
- EMFCQ (but not ELICQ) and RA hold at $\bar{x}$, and
- EMFCQ holds at $\bar{x}$ but RA does not hold at $\bar{x}$.

We will not recall these (very technical) characterizations here; however, we will use strongly stable stationary points in the following description of structural stability of an SIP problem. We also refer to Günzel and Jongen [25], where the relationship between strong stability and MFCQ is considered. Now, we define a structurally stable SIP problem.

Definition 1.

- (a) For $\gamma \in \mathbb{R}$ define the feasible lower level set as

$$N^\gamma(f, G) = \{x \in M \mid f(x) \leq \gamma\}.$$

- (b) Consider two SIP problems $SIP(f, G)$ and $SIP(\tilde{f}, \tilde{G})$, which are defined by their objective functions f and $\tilde{f}$ as well as their constraints G and $\tilde{G}$, respectively. These problems $SIP(f, G)$ and $SIP(\tilde{f}, \tilde{G})$ are called *equivalent* (notation: $SIP(f, G) \sim SIP(\tilde{f}, \tilde{G})$) if there exist continuous mappings $\varphi^1 : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}^n$, $\varphi^2 : \mathbb{R} \rightarrow \mathbb{R}$ with the following properties:

- $\varphi^1(\gamma, \cdot)$ is a homeomorphism for each $\gamma \in \mathbb{R}$.
- φ^2 is a homeomorphism and monotonically increasing.
- For all $\gamma \in \mathbb{R}$ we have $\varphi^1(\gamma, [N^\gamma(f, G)]) = N^{\varphi^2(\gamma)}(\tilde{f}, \tilde{G})$.

- (c) The (original) problem $SIP = SIP(f, G)$ is called structurally stable if there exist C_s^2 - neighborhoods F^1 of f and F^2 of G such that $SIP(f, G) \sim SIP(\tilde{f}, \tilde{G})$ for all $(\tilde{f}, \tilde{G}) \in F^1 \times F^2$.

The next theorem provides an equivalent characterization of structural stability.

Theorem 7. *Structural stability of SIP [23]:*

Suppose that M is a compact set. Then, the problem $SIP(= SIP(f; G))$ is structurally stable if and only if the following three conditions are fulfilled:

- (a) *EMFCQ holds at all $x \in M$.*
- (b) *Every stationary point of SIP is strongly stable.*
- (c) *Different stationary points of SIP have different objective function values.*

FINAL REMARKS

In this article we discussed very briefly a few basic features of SIP. In contrast to finite programming an SIP problem has infinitely many inequality constraints. Such problems arise, for example, in approximation theory, optimal control, or in applications from engineering, finance, and economics that are characterized by at least one parameter varying in a compact given domain (representing e.g., time, geographic area, frequency, and price) and a corresponding inequality constraint for each feasible parameter value.

It is obvious that we could not cover all the important properties of an SIP problem here. However, we conclude with some references on two other important features.

Solution Methods

As mentioned above there are two main challenges for the design of solution methods in SIP:

- There exist infinitely many inequality constraints and, therefore, each solution approach has to transform the original problem in a (sequence of) finite programming problem(s).

- For the calculation of active constraints a corresponding global optimization problem has to be solved.

Since the 1990s, there exist solution methods that use discretization techniques or assume that RA holds at the considered iteration points [2,26,27]. Recently more advanced techniques have been developed, we refer for example to

- interval methods and adaptive convexification methods (using special tools from global optimization) [28–31],
- smoothing methods [32,33],
- interior point and bilevel methods [34,35].

Generalized Semiinfinite Programming

Finally, we refer to the broader class of so-called *generalized semi-infinite programming* (GSIP) problems, which allows that the index set depends additionally on the vector x of decision variables.

A GSIP problem is defined as

$$\text{GSIP: minimize } f(x) \text{ subject to } x \in M^{\text{GSIP}},$$

where

$$M^{\text{GSIP}} = \{x \in \mathbb{R}^n \mid G(x, y) \geq 0, y \in Y(x)\}$$

and

$$Y(x) = \{y \in \mathbb{R}^r \mid u_l(x, y) = 0, l \in A, v_k(x, y) \leq 0, k \in B\}.$$

Here, Y is substituted by $Y(x)$ and, not surprisingly, the structure of this problem can become much more complicated than that in the standard SIP case. We will illustrate this by recalling the following example

Example 2 [Example 3.3 in Guerra-Vázquez *et al.* [2]]. Consider the feasible set

$$M^{\text{GSIP}} = \{x \in \mathbb{R}^2 \mid y \geq 0, y \in Y(x)\}$$

and the index set

$$Y(x) = \{y \in \mathbb{R} \mid y \geq x_1, y \leq x_2\}.$$

Then, the feasible set can be rewritten as

$$M^{\text{GSIP}} = \left\{x \in \mathbb{R}^2 \mid x_1 \leq x_2, x_1 \geq 0\right\} \\ \cup \left\{x \in \mathbb{R}^2 \mid x_1 > x_2\right\}.$$

We see that

- M^{GSIP} is not closed; and
- it is the *union* (and not the intersection as in the standard case) of half-spaces.

The possible *nonclosedness* of the feasible set and its possible *disjunctive structure* are topological phenomena which cannot appear in standard SIP. They have a strong impact on the theory of GSIP (e.g., optimality conditions, and stability properties) and on the design of solution methods. For more information on this subject see the tutorial paper [2] and recent papers [36–38].

SEMI-MARKOV DECISION PROCESSES

MELIKE BAYKAL-GÜRSOY
Department of Industrial and
Systems Engineering, RUTCOR,
CAIT, Rutgers University, New
Brunswick, New Jersey

INTRODUCTION

Semi-Markov decision processes (SMDPs) are used in modeling stochastic control problems arising in Markovian dynamic systems, where the sojourn time in each state is a general continuous random variable. They are powerful, natural tools for the optimization of queues [1–7], production scheduling [8–11], and reliability/maintenance [12].

For example, in a machine replacement problem with deteriorating performance over time, a decision maker, after observing the current state of the machine, decides whether to continue its usage, or initiate a maintenance (preventive or corrective) repair, or replace the machine. There are a reward or cost structure associated with the states and decisions, and an information pattern available to the decision maker. This decision depends on a performance measure over the planning horizon which is either finite or infinite, such as total expected discounted or long run average expected reward/cost with or without external constraints, and variance penalized average reward.

SMDPs are based on semi-Markov processes (SMPs) [13] (see also *Semi-Markov Processes* SMPs), that include renewal processes (see also *Definition and Examples of Renewal Processes*) and continuous-time Markov chains (CTMCs) (see also *Definition and Examples of Continuous-Time Markov Chains*) as special cases. In an SMP similar to Markov chains (DTMCs) (see also *Definition and Examples of DTMCs*), state changes occur according to the Markov

property, that is, states in the future do not depend on the states in the past given the present. However, the sojourn time in a state is a continuous random variable with distribution depending on that state and the next state, a Markov chain is a SMP in which the sojourn times are discrete (geometric) random variables independent of the next state; a CTMC is a SMP with exponentially distributed sojourn times; and a renewal process is a SMP with a single state. SMDPs, first introduced by Jewell [14] and De Cani [15], are also called as *Markov renewal programs* [16–19].

This article is organized as follows: the next section introduces basic definitions and notations. Various performance criteria are presented in the section titled “Performance Measures” and their solution methodologies are described in the sections titled “Discounted Reward Criterion,” “Average Reward Criterion,” and “Expected Time-Average Reward and Variability.”

BASIC DEFINITIONS

We consider time-homogeneous, finite state, and finite action SMDPs, and give references for the more general cases. Let $\{X_m, m \geq 0\}$ denote the state process, which takes values in a finite state space $\mathcal{S}$. We also use $\{X_m, m \in \mathcal{N}\}$ to denote the state process with $\mathcal{N}$ representing the set of nonnegative integers. At each epoch m , the decision maker chooses an action A_m from a finite action space $\mathcal{A}$. The sojourn time between the $(m - 1)$ -st and the (m) th epochs is a random variable and denoted by γ_m . The underlying sample-space $\Omega = \{\mathcal{S} \times \mathcal{A} \times (0, \infty)\}^\infty$ consists of all possible realizations of states, actions, and the transition times. Throughout, the sample space will be equipped with the σ -algebra generated by the random variables $\{X_m, A_m, \gamma_{m+1}; m \geq 0\}$. The initial state is assumed to be fixed and given. Note that we will suppress the dependence on the initial state unless given otherwise. Denote

P_{xy} , $x \in \mathcal{S}$, $a \in \mathcal{A}$, $y \in \mathcal{S}$, for the law of motion of the process, that is, for all policies $\mathbf{u}$ and all epochs m

$$P_{\mathbf{u}}\{X_{m+1} = y | X_0, A_0, \Upsilon_1, \dots, X_m = x, A_m = a\} = P_{xy}.$$

Also conditioned on the event that the next state is y , Υ_{m+1} has the distribution function $F_{xy}(\cdot)$, that is,

$$P_{\mathbf{u}}\{\Upsilon_{m+1} \leq t | X_0, A_0, \Upsilon_1, \dots, X_m = x, A_m = a, X_{m+1} = y\} = F_{xy}(t).$$

Assume that $F_{xy}(0) < 1$.

The process $\{S_t, B_t : t \geq 0\}$, where S_t is the state of the process at time t , and B_t is the action taken at time t , is referred to as the *SMDP*. Let $T_n = \sum_{m=1}^n \Upsilon_m$, that is, denote the time of n th transition. For $t \in [T_m, T_{m+1})$, clearly

$$S_t = X_m, \quad B_t = A_m.$$

Policy Types

A *decision rule* $\mathbf{u}^m$ at epoch m is a vector consisting of probabilities assigned to each available action. A decision rule may depend on all of the previous states, actions, transition times, and the present state. Let u_a^m denote the a th component of $\mathbf{u}^m$. Thus, it is the conditional probability of choosing action a at the m -th epoch, that is,

$$P_{\mathbf{u}}\{A_m = a | X_0 = x_0, A_0 = a_0, \Upsilon_1 = \tau_1, \dots, X_m = x\} = u_a^m(x_0, a_0, \tau_1, \dots, x).$$

A *policy* is an infinite sequence of decision rules $\mathbf{u} = \{\mathbf{u}^0, \mathbf{u}^1, \mathbf{u}^2, \dots\}$.

Policy $\mathbf{u}$ is called *Markov policy* if $\mathbf{u}^m$ at epoch m depends only on the current state not the past history, that is,

$$\mathbf{u}^m(x) = \mathbf{u}_a^m(x_0, a_0, \tau_1, \dots, x).$$

A policy is called *stationary* if the decision rule at each epoch is the same and it depends only on the present state of the process, $\mathbf{u} = \{\mathbf{u}, \mathbf{u}, \mathbf{u}, \dots\}$; denote f_{xa} for the probability of choosing action a when in state x . A

stationary policy is said to be *pure* if for each $x \in \mathcal{S}$ there is only one action $a \in \mathcal{A}$ such that $f_{xa} = 1$. Let U, M, F , and G denote the set of all policies, Markov policies, stationary policies, and pure policies, respectively. Clearly, $G \subset F \subset M \subset U$.

Under a stationary policy $\mathbf{f}$, the state process $\{S_t : t \geq 0\}$ is a SMP, while the process $\{X_m : m \in \mathcal{N}\}$ is the embedded Markov chain with transition probabilities

$$P_{xy}(\mathbf{f}) = \sum_{a \in \mathcal{A}} P_{xy} f_{xa}.$$

Clearly, the process $\{S_t, B_t : t \geq 0\}$ is also a SMP under a stationary policy $\mathbf{f}$ with the embedded Markov chain $\{X_m, A_m : m \in \mathcal{N}\}$.

Chain Structure

Under a stationary policy $\mathbf{f}$, state x is *recurrent* if and only if x is recurrent in the embedded Markov chain; similarly, x is *transient* if and only if x is transient for the embedded Markov chain. A SMDP is said to be *unichain* (*multichain*) if the embedded Markov chain for each pure policy is unichain (multichain), that is, if the transition matrix $P(\mathbf{g})$ has at most one (more than one) recurrent class plus (a perhaps empty) set of transient states for all pure policies $\mathbf{g}$. It is called *irreducible* if $P(\mathbf{g})$ is irreducible under all pure policies $\mathbf{g}$. Similarly, a SMDP is said to be *communicating* if $P(\mathbf{f})$ is irreducible for all stationary policies that satisfy $f_{xa} > 0$, for all $x \in \mathcal{S}$, $a \in \mathcal{A}$.

Let $\tau(x, a)$ define the expected sojourn time given that the state is x and the action a is chosen just before a transition, that is,

$$\begin{aligned} \tau(x, a) &\triangleq E_{\mathbf{u}}[\Upsilon_m | X_{m-1} = x, A_{m-1} = a] \\ &= \int_0^\infty \sum_{y \in \mathcal{S}} P_{\mathbf{u}}\{X_m = y, \Upsilon_m > t \\ &\quad | X_{m-1} = x, A_{m-1} = a\} dt \\ &= \int_0^\infty \left[1 - \sum_{y \in \mathcal{S}} P_{xy} F_{xy}(t) \right] dt. \end{aligned}$$

Let $W_t(x, a)$ denote the random variables representing the state-action intensities,

$$W_t(x, a) \triangleq \frac{1}{t} \int_0^t \mathbf{1}\{(S_s, B_s) = (x, a)\} ds,$$

where $\mathbf{1}\{\cdot\}$ denotes the indicator function. Let U_0 denote the class of all policies $\mathbf{u}$ such that $\{W_t(x, a); t \geq 0\}$ converges. Thus, for $\mathbf{u} \in U_0$, there exist random variables $\{W(x, a)\}$ such that

$$\lim_{t \rightarrow \infty} W_t(x, a) = W(x, a).$$

Let U_1 be the class of all policies $\mathbf{u}$ such that the expected state-action intensities $\{E_{\mathbf{u}}[W_t(x, a)]; t \geq 0\}$ converge for all x and a . For $\mathbf{u} \in U_1$ denote

$$w_{\mathbf{u}}(x, a) = \lim_{t \rightarrow \infty} E_{\mathbf{u}}[W_t(x, a)].$$

From Lebesgue's Dominated Convergence Theorem $U_0 \subset U_1$.

A well-known result from renewal theory [13] is that if $\{Y_t = (S_t, B_t) : t \geq 0\}$ is a homogeneous SMP, and if the embedded Markov chain $\{X_m, m \in \mathcal{N}\}$ is unichain then, the proportion of time spent in state y , that is,

$$\lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t \mathbf{1}\{Y_s = y\} ds,$$

exists. Since under a stationary policy $\mathbf{f}$, the process $\{Y_t = (S_t, B_t) : t \geq 0\}$ is a homogeneous SMP, if the embedded Markov decision process is unichain, then the limit of $W_t(x, a)$ as t goes to infinity exists and the proportion of time spent in state x when action a is applied is given as

$$W(x, a) = \lim_{t \rightarrow \infty} W_t(x, a) = \frac{\tau(x, a) Z(x, a)}{\sum_{x, a} \tau(x, a) Z(x, a)},$$

where $Z(x, a)$ denotes the associated state-action frequencies. Let $\{z_{\mathbf{f}}(x, a); x \in \mathcal{S}, a \in \mathcal{A}\}$ denote the expected state-action frequencies, that is,

$$\begin{aligned} z_{\mathbf{f}}(x, a) &= \lim_{n \rightarrow \infty} E_{\mathbf{f}} \frac{1}{n} \sum_{m=1}^n \mathbf{1}\{X_{m-1} = x, A_{m-1} = a\} \\ &= \pi_x(\mathbf{f}) f_{xa}, \end{aligned}$$

where $\pi_x(\mathbf{f})$ is the steady-state distribution of the embedded Markov chain $P(\mathbf{f})$.

The long run average number of transitions into state x when action a is applied per

unit time is,

$$\begin{aligned} v_{\mathbf{f}}(x, a) &= \frac{\pi_x(\mathbf{f}) f_{xa}}{\sum_{x, a} \tau(x, a) \pi_x(\mathbf{f}) f_{xa}} \\ &= \frac{z_{\mathbf{f}}(x, a)}{\sum_{x, a} \tau(x, a) z_{\mathbf{f}}(x, a)}. \end{aligned} \quad (1)$$

This gives $w_{\mathbf{f}}(x, a) = \tau(x, a) v_{\mathbf{f}}(x, a)$.

Reward Structure

Let R_t be the reward function at time t . R_t can be an impulse function corresponding to the reward earned immediately at a transition epoch and/or it can be a step function between transition epochs corresponding to the rate of reward as described below. The decision maker earns an immediate reward $R(X_m, A_m)$ and a reward with rate $r(X_m, A_m)$ until the $(m + 1)$ -th epoch, that is,

$$R_t = \begin{cases} R(X_m, A_m), & \text{if } t = T_m, \\ r(X_m, A_m), & \text{if } t \in [T_m, T_{m+1}). \end{cases} \quad (2)$$

Thus,

$$R_{m+1} = R(X_m, A_m) + r(X_m, A_m) \Upsilon_{m+1},$$

is the reward earned during the $(m + 1)$ -th transition [20–22].

Similarly, there is an immediate cost $C(X_m, A_m)$ and a cost with rate $c(X_m, A_m)$ with

$$C_{m+1} = C(X_m, A_m) + c(X_m, A_m) \Upsilon_{m+1}.$$

Hence, at any epoch if the process is in state $x \in \mathcal{S}$ and action $a \in \mathcal{A}$ is chosen, then the reward earned during this epoch is represented by $\bar{r}(x, a) \triangleq R(x, a) + r(x, a) \tau(x, a)$. Similarly, the cost during this epoch is represented by $\bar{c}(x, a) \triangleq C(x, a) + c(x, a) \tau(x, a)$.

Example 1. Consider the *machine replacement problem* mentioned in the section titled “Introduction” with states (1) machine is in good condition, (2) machine has some minor problems, (3) machine is down and needs to be replaced. Time to failure of the machine follows a Weibull distribution with scale parameter equal to 8000 h and shape parameter

equal to 4. The failure is minor with probability 0.95 and major requiring replacement of the machine with probability 0.05. Life time of a machine with minor problems follows a Weibull distribution with scale parameter equal to 20,000 h and shape parameter equal to 4. However, a machine with minor problems could be maintenance repaired to make it as good as new. Maintenance repair takes Weibull distributed amount of time with scale parameter equal to 8 h and shape parameter equal to 0.5. On the other hand, the machine replacement time is normally distributed with mean 72 h and variance of 8 h. Running a fully working machine earns \$100/h, and a machine with minor problem earns \$75/h profit. It costs \$40/h to repair and \$10,000 to replace a machine. Note that there is no control action available in states 1 and 3. In state 1 the decision maker needs to “wait” and in state 3 s/he needs to order a new machine. Let us denote this action as action 1. In state 2, there are two possible actions to choose: “wait” action denoted as action 1, and “initiate repair” denoted as action 2. Parameters of this model are:

$$P_{113} = 0.95, \quad P_{113} = 0.05, \quad P_{213} = 1, \\ P_{221} = 1, \quad P_{311} = 1,$$

$$\tau(1, 1) = 7252, \quad \tau(2, 1) = 1813, \\ \tau(2, 2) = 48, \quad \tau(3, 1) = 72, \\ \bar{\tau}(1, 1) = 725,200, \quad \bar{\tau}(2, 1) = 135,975, \\ \bar{\tau}(2, 2) = -1920, \quad \bar{\tau}(3, 1) = -10,000.$$

The last two reward values correspond to the incurred costs under repair and replacement, respectively.

PERFORMANCE MEASURES

We will focus on the optimality criteria over the infinite horizon, since some general results could be obtained for these models. We will first consider finding a policy $\mathbf{u}$ that

will maximize the *total discounted reward* defined as

$$\phi_\alpha(\mathbf{u}) \triangleq E_{\mathbf{u}} \left[\int_0^\infty e^{-\alpha s} R_s ds \right], \quad (3)$$

where α represents the discount factor [14,23–26]. Discounted reward optimality criterion is easier to analyze and understand than the average reward criterion, because the results for these models hold regardless of the chain structure of the embedded Markov chain. In fact, the existence of this integral is immediate under finite rewards. In addition, discounting lands itself naturally in economic problems in which the present value of future earnings is discounted as a function of the interest rate. Another interpretation of these models implies the importance of the initial decisions.

The great majority of the literature, on the other hand, is concerned with the *long run average expected reward* criterion with

$$\phi_1(\mathbf{u}) \triangleq \liminf_{t \rightarrow \infty} \frac{1}{t} E_{\mathbf{u}} \left[\int_0^t R_s ds \right], \quad (4)$$

ϕ_1 denoting the *long run average expected reward* [14,17,22,27–29]. The following alternative to ϕ_1 is given by Jewell [30], Ross [31,32], and Mine and Osaki [18] as

$$\phi_2(\mathbf{u}) \triangleq \liminf_{n \rightarrow \infty} \frac{E_{\mathbf{u}} \left[\sum_{m=1}^n R_m \right]}{E_{\mathbf{u}}[T_n]}, \quad (5)$$

referred to as the *ratio-average reward* [33]. The performance measure ϕ_2 is also used by other researchers [7,14,34–38].

Let

$$\phi_\alpha^* = \sup_{\mathbf{u} \in U} \phi_\alpha(\mathbf{u}), \quad \phi_1^* = \sup_{\mathbf{u} \in U} \phi_1(\mathbf{u}), \\ \phi_2^* = \sup_{\mathbf{u} \in U} \phi_2(\mathbf{u}).$$

A policy $\mathbf{u}$ is optimal for $\phi_\alpha(\cdot)$ if $\phi_\alpha(\mathbf{u}) = \phi_\alpha^*$. For a fixed $\epsilon > 0$, a policy $\mathbf{u}$ is ϵ -optimal for $\phi_\alpha(\cdot)$ if $\phi_\alpha(\mathbf{u}) > \phi_\alpha^* - \epsilon$. Optimality and ϵ -optimal for $\phi_1(\cdot)$, $\phi_2(\cdot)$ and the other performance measures we consider in this article are defined analogously.

The following *expected time-average reward* criterion has been considered recently by Baykal-Gürsoy and Gürsoy [39–41]

$$\psi(\mathbf{u}) \triangleq E_{\mathbf{u}} \left[\liminf_{t \rightarrow \infty} \frac{1}{t} \int_0^t R_s ds \right] \quad (6)$$

subject to the sample path constraint,

$$P_{\mathbf{u}} \left\{ \limsup_{t \rightarrow \infty} \frac{1}{t} \int_0^t C_s ds \leq \gamma \right\} = 1. \quad (7)$$

This constraint requires that the long-run average costs on almost all sample paths should be bounded by γ .

More generally, they investigate the following *expected time-average variability*

$$v(\mathbf{u}) \triangleq E_{\mathbf{u}} \left[\liminf_{t \rightarrow \infty} \frac{1}{t} \int_0^t h(R_s, \frac{1}{t} \int_0^t R_q dq) ds \right], \quad (8)$$

where $h(\cdot, \cdot)$ is a continuous function of the current reward at time s and the average reward over an interval that includes time s . By letting $v^* = \sup_{\mathbf{u} \in U} v(\mathbf{u})$, the optimality and ϵ -optimality for $v(\cdot)$ are analogously defined.

DISCOUNTED REWARD CRITERION

Discounted reward can be rewritten as:

$$\begin{aligned} \phi_{\alpha}(\mathbf{u}) &= E_{\mathbf{u}} \left[\sum_{m=0}^{\infty} e^{-\alpha T_m} \left(R(X_m, A_m) \right. \right. \\ &\quad \left. \left. + \frac{r(X_m, A_m)}{\alpha} (1 - e^{-\alpha \Upsilon_m}) \right) \right] \\ &= \sum_{m=0}^{\infty} \sum_{x,a} \int_0^{\infty} e^{-\alpha t} \left[R(x, a) + \frac{r(x, a)}{\alpha} \right. \\ &\quad \left. \times \left(1 - \sum_y P_{xay} \int_0^{\infty} e^{-\alpha \tau} dF_{xay}(\tau) \right) \right] \\ &\quad P_{\mathbf{u}} \{X_m = x, A_m = a, T_m \leq t\}. \end{aligned}$$

The terms inside the second integral could be recognized as the Laplace transform of the density function $f_{xay}(\cdot)$ and will be denoted as $\tilde{f}_{xay}(\alpha)$.

The optimal discounted reward vector is represented by ϕ_{α}^{*x} for each initial state x , and

it can be shown that it satisfies the optimality equation for all $x \in S$:

$$\begin{aligned} \phi_{\alpha}^x &= \max_a \left\{ \left[R(x, a) + \frac{r(x, a)}{\alpha} \left(1 - \sum_j P_{xaj} \tilde{f}_{xaj} \right) \right] \right. \\ &\quad \left. + \sum_y P_{xay} \tilde{f}_{xay}(\alpha) \phi_{\alpha}^y \right\} \\ &= \max_a \left\{ r^{\alpha}(x, a) + \sum_y P_{xay}^{\alpha} \phi_{\alpha}^y \right\}. \quad (9) \end{aligned}$$

Second equality is obtained from the first by denoting the terms inside the square bracket as $r^{\alpha}(x, a)$ and writing $P_{xay} \tilde{f}_{xay}(\alpha)$ as P_{xay}^{α} . Note that the second equality is similar to the one obtained for the Markov Decision Processes (MDPs) (see also **Total Expected Discounted Reward MDPs: Existence of Optimal Policies**). Thus, discounted SMDPs can be reduced to discounted MDPs by using these transformations. Since $P_{xay}^{\alpha} < 1$, the right hand side of the optimality Equation (9) is a contraction mapping and the next theorem is immediate.

Theorem 1. *For SMDPs under the discounted reward criterion:*

- *There exists a unique solution to the optimality equation (9) and it is equal to ϕ_{α}^* .*
- *There exists an optimal pure policy $\mathbf{g}^*$ given by, $\phi_{\alpha}(\mathbf{g}^*) = \phi_{\alpha}^* = (I - P_{xay}^{\alpha})^{-1} r^{\alpha}(\mathbf{g}^*)$ where $r^{\alpha}(\mathbf{g}^*)$ denotes the single-period discounted reward earned under policy $\mathbf{g}^*$.*

This optimal pure policy could be obtained using the policy iteration (see also **Total Expected Discounted Reward MDPs: Policy Iteration Algorithm**), value iteration (see also **Total Expected Discounted Reward MDPs: Value Iteration Algorithm**), or linear programming (LP) algorithms [5–7,38]. The LP algorithm is discussed next. Consider the following LP

with given numbers $\beta_x > 0$ for $x \in \mathcal{S}$.

$$\begin{aligned} & \max \sum_{x \in \mathcal{S}, a \in \mathcal{A}} r^\alpha(x, a) z(x, a) \\ & \text{s.t.} \sum_{x \in \mathcal{S}, a \in \mathcal{A}} (\delta_{xy} - P_{xay}^\alpha) z(x, a) = \beta_y, \quad y \in \mathcal{S} \\ & \quad z(x, a) \geq 0, \quad x \in \mathcal{S}, a \in \mathcal{A}. \end{aligned}$$

Let $\mathbf{z}^*$ be an optimum solution of the above LP. Clearly, any extreme point of this LP has $|\mathcal{S}|$ number of basic variables, where $|\cdot|$ denotes the number of elements in a given set. Thus, $\mathbf{z}^*(x, a)$ is positive only for one action a . The optimum pure policy $\mathbf{g}^*$ is then obtained by assigning $\mathbf{g}_x^*$ in such a way that $\mathbf{z}^*(x, \mathbf{g}_x^*) > 0$. Constraints defined in a similar fashion,

$$E_{\mathbf{u}} \left[\int_0^\infty e^{-as} C_s ds \right] < \gamma,$$

could be included into the LP as

$$\sum_{x \in \mathcal{S}, a \in \mathcal{A}} c^\alpha(x, a) z(x, a) < \gamma,$$

with $c^\alpha(x, a) = C(x, a) + \frac{c(x, a)}{\alpha} (1 - \sum_y P_{xay} \tilde{f}_{xay})$. Since every new constraint will increase the number of basic variables, the optimum policy will no longer be pure but randomized stationary [24].

For the countable state case, we need the assumption,

Assumption 1. There exists $\delta > 0$ and $\varepsilon > 0$, such that

$$F_{xay}(\delta) \leq 1 - \varepsilon \quad \text{for all } x \text{ and } y \in \mathcal{S} \text{ and } a \in \mathcal{A},$$

together with $|r^\alpha(x, a)| \leq M < \infty$ to ensure the existence of an optimal pure policy. Additional conditions are required for SMDPs with Borel state and action spaces, and unbounded rewards [21, 24, 38].

AVERAGE REWARD CRITERION

Average or *ratio-average* expected reward criterion is applied to systems in which the system dynamics is not slow enough to

warrant discounting. This criterion is more difficult to analyze since the existence of the optimal stationary policy depends on the chain structure. Under the condition that the SMDP is irreducible, $\phi_1(\mathbf{f}) = \phi_2(\mathbf{f})$ for every stationary policy $\mathbf{f}$ [18, 31]. However, this may not hold even for unichain SMDPs [33]. While ϕ_1 is clearly the more appealing criterion, it is easier to write the optimality equations when establishing the existence of an optimal pure policy under criterion ϕ_2 [22, 29, 42]. On the other hand, for finite state and finite action SMDPs, there exists an optimal pure policy under ϕ_1 [27, 29, 42], while such an optimal policy may not exist under ϕ_2 in a general multichain SMDP [43]. Jianyong and Xiaobo [43] investigate average reward SMDPs focusing on ϕ_2 and using a data-transformation method [19]. They show that the optimal pure policy exists in some special cases such as the unichain case and the weakly communicating case.

The optimal pure policy for the average expected reward criterion in multichain SMDPs is obtained from the optimal solution of the following LP [25] under the assumption on the sojourn times.

$$\begin{aligned} & \max \sum_{x \in \mathcal{S}, a \in \mathcal{A}} \bar{r}(x, a) v(x, a) \\ & \text{s.t.} \sum_{x \in \mathcal{S}, a \in \mathcal{A}} (\delta_{xy} - P_{xay}) v(x, a) = 0, \quad y \in \mathcal{S} \\ & \quad \sum_{a \in \mathcal{A}} \tau(y, a) v(y, a) \\ & \quad + \sum_{x \in \mathcal{S}, a \in \mathcal{A}} (\delta_{xy} - P_{xay}) t(x, a) = \beta_y, \quad y \in \mathcal{S} \\ & \quad v(x, a) \geq 0, \quad t(x, a) \geq 0 \quad x \in \mathcal{S}, a \in \mathcal{A}, \end{aligned}$$

where $\beta_x > 0$ for $x \in \mathcal{S}$ and $\sum_y \beta_y = 1$. The optimum average expected reward for each initial state is obtained from the dual of this LP.

In the unichain case, the average reward remains constant regardless of the initial

state, and the LP reduces to

$$\begin{aligned} \phi_1^* &= \max \sum_{x \in \mathcal{S}, a \in \mathcal{A}} \bar{r}(x, a) v(x, a) \\ \text{s.t. } &\sum_{x \in \mathcal{S}, a \in \mathcal{A}} (\delta_{xy} - P_{xay}) v(x, a) = 0, \quad y \in \mathcal{S} \\ &\sum_{x \in \mathcal{S}, a \in \mathcal{A}} \tau(y, a) v(y, a) = 1 \\ &v(x, a) \geq 0, \quad x \in \mathcal{S}, a \in \mathcal{A}, \end{aligned}$$

with the optimum solution denoted as $\mathbf{v}^*$. The optimum pure policy $\mathbf{g}^*$ is then obtained by assigning $\mathbf{g}_x^*$ in such a way that $v^*(x, \mathbf{g}_x^*) > 0$. The optimality equations are given for each state x by

$$\zeta_x = \max_a \left\{ \bar{r}(x, a) - g\tau(x, a) + \sum_y P_{xay} \zeta_y \right\}.$$

The solution to these equations, $\{\zeta^*, \mathbf{g}^*\}$ provides the optimum average expected reward, $\phi_1^* = \mathbf{g}^*$.

The constrained problem has been investigated for the average reward SMDPs [20,33,34]. Beutler and Ross [20,34] consider the ratio-average reward with a constraint under a condition stronger than the unichain condition. In Ref. 33, Feinberg examines the problem of maximizing both ϕ_1 and ϕ_2 , subject to a number of constraints. Under the condition that the initial distribution is fixed, he shows that for both criteria, there exist optimal mixed stationary policies when an associated LP is feasible. The mixed policies are defined as policies with an initial one-step randomization applied to a set of pure policies, hence they are not stationary. He provides an LP algorithm for the unichain SMDP under both criteria. Average expected reward SMDPs with Borel state and action spaces and unbounded rewards are considered by Schäl [42], Sennott [21], and Luque-Vásquez and Hernández-Lerma [44].

EXPECTED TIME-AVERAGE REWARD AND VARIABILITY

The expected time-average reward criterion is similar to the average expected reward criterion. Fatou's lemma immediately implies

that $\psi(\mathbf{u}) \leq \phi_1(\mathbf{u})$ holds for all policies. Baykal-Gürsoy and Gürsoy [40] show that for a large class of policies, these two rewards are equal and an ϵ -optimal randomized stationary policy can be obtained for the general (communicating, multichain) SMDP, while such a policy may not exist for the average reward problem [40]. Multiple constraints and the more general expected time-average variability criterion are also discussed. They show that an ϵ -optimal stationary policy can be obtained for the general SMDPs. If $h(x, y) = x - \lambda(x - y)^2$, then the optimal policy is a pure policy. Note that in this case maximizing $v(\mathbf{u})$ corresponds to maximizing the expected average reward penalized by the expected average variability. A decomposition algorithm to locate the ϵ -optimal stationary policy for both problems is given in Ref. 40. This algorithm utilizes an LP of the form:

$$\begin{aligned} \max &\sum_{x \in \mathcal{S}, a \in \mathcal{A}} h \left[\bar{r}(x, a), \sum_{y \in \mathcal{S}, b \in \mathcal{A}} \bar{r}(y, b) v(y, b) \right] v(x, a) \\ \text{s.t. } &\sum_{x \in \mathcal{S}, a \in \mathcal{A}} (\delta_{xy} - P_{xay}) v(x, a) = 0, \quad y \in \mathcal{S} \\ &\sum_{x \in \mathcal{S}, a \in \mathcal{A}} \tau(x, a) v(x, a) = 1 \\ &\sum_{x \in \mathcal{S}, a \in \mathcal{A}} \bar{c}(x, a) v(x, a) \leq \gamma \\ &v(x, a) \geq 0, \quad x \in \mathcal{S}, a \in \mathcal{A}. \end{aligned}$$

MARKOV RENEWAL AND SEMI-MARKOV PROCESSES

Semi-Markov processes (SMPs) were introduced independently by W.L. Smith and P. Lévy in the same Mathematical meeting in 1954. SMPs constitute a generalization of Markov and renewal processes. Jump Markov processes, Markov chains, renewal processes—ordinary, alternating, delayed, and stopped—are particular cases of SMPs. As Feller [1] pointed out, the basic theory of SMPs was introduced by Pyke [2,3]. Further significant results have been obtained by Pyke and Schaufele [4,5], Çinlar [6,7], Koroliuk [8–10], and many others. Also, see Refs 11 and 12. Currently, SMPs have achieved significant importance in probabilistic and statistical modeling. Our main references for this article are Refs 13–15.

Consider an infinite countable set, say E , and an E -valued pure jump stochastic process $Z = (Z_t)_{t \in \mathbb{R}_+}$. Let $0 = S_0 \leq S_1 \leq \dots \leq S_n \leq S_{n+1} \leq \dots$ be the jump times of Z , and $J_0, J_1, J_2, \dots$ the successive visited states of Z . Note that S_0 may also take positive values. Let $\mathbb{N}$ be the set of nonnegative integers.

Definition 1. The stochastic process $(J_n, S_n)_{n \in \mathbb{N}}$ is said to be a Markov renewal process (MRP), with state space E , if it satisfies a.s., the following equality

$$\begin{aligned} \mathbb{P}(J_{n+1} = j, S_{n+1} - S_n \leq t \mid J_0, \dots, J_n; \\ S_1, \dots, S_n) \\ = \mathbb{P}(J_{n+1} = j, S_{n+1} - S_n \leq t \mid J_n) \end{aligned}$$

for all $j \in E$, all $t \in \mathbb{R}_+$ and all $n \in \mathbb{N}$. In this case, Z is called a *semi-Markov process*.

We assume that the above probability is independent of n and S_n , and, in this case, the MRP is called *time homogeneous*. The MRP $(J_n, S_n)_{n \in \mathbb{N}}$ is determined by the transition kernel $Q_{ij}(t) := \mathbb{P}(J_{n+1} = j, S_{n+1} - S_n \leq t \mid J_n = i)$, called the *semi-Markov kernel*, and the *initial distribution* α , with $\alpha(i) = \mathbb{P}(J_0 = i)$, $i \in E$. The process (J_n) is a Markov chain with state space E and transition probabilities $P(i, j) := Q_{ij}(\infty) := \lim_{t \rightarrow \infty} Q_{ij}(t)$, called the *embedded Markov chain (EMC)* of Z . It is worth noticing that here $Q_{ii}(t) \equiv 0$, for all $i \in E$, but in general we can consider semi-Markov kernels by dropping this hypothesis.

The SMP Z is connected to (J_n, S_n) by

$$\begin{aligned} Z_t = J_n, \text{ if } S_n \leq t < S_{n+1}, t \geq 0 \quad \text{and} \\ J_n = Z_{S_n}, n \geq 0. \end{aligned}$$

A Markov process with state space $E = \mathbb{N}$ and generating matrix $A = (a_{ij})_{i, j \in E}$ is a special SMP with semi-Markov kernel

$$Q_{ij}(t) = \frac{a_{ij}}{a_i}(1 - e^{-a_i t}), \quad i \neq j, \quad a_i \neq 0,$$

where $a_i := -a_{ii}$, $i \in E$, and $Q_{ij}(t) = 0$, if $i = j$ or $a_i = 0$.

Also, define $X_n := S_n - S_{n-1}$, $n \geq 1$, the interjump times, and the process $(N(t))_{t \in \mathbb{R}_+}$, which counts the number of jumps of Z in the time interval $(0, t]$, by $N(t) := \sup\{n \geq 0 : S_n \leq t\}$. Also, define $N_i(t)$ to be the number of visits of Z to state $i \in E$ in the time interval $(0, t]$. To be specific,

$$N_i(t) := \sum_{n=1}^{N(t)} \mathbf{1}_{\{J_n=i\}} = \sum_{n=1}^{\infty} \mathbf{1}_{\{J_n=i, S_n \leq t\}},$$

and also

$$N_i^*(t) = \mathbf{1}_{\{J_0=i, S_0 \leq t\}} + N_i(t).$$

If we consider the (eventually delayed) renewal process $(S_n^i)_{n \geq 0}$ of successive times

of visits to state i , then $N_i(t)$ is the counting process of renewals. Denote by μ_{ii} the mean recurrence time of (S_n^i) , that is, $\mu_{ii} = \mathbb{E}[S_2^i - S_1^i]$.

Let us denote by $Q(t) = (Q_{ij}(t), i, j \in E)$, $t \geq 0$, the semi-Markov kernel of Z . Then we can write

$$\begin{aligned} Q_{ij}(t) &:= \mathbb{P}(J_{n+1} = j, X_{n+1} \leq t \mid J_n = i) \\ &= P(i, j)F_{ij}(t), \quad t \geq 0, \quad i, j \in E, \end{aligned} \quad (1)$$

where $P(i, j) := \mathbb{P}(J_{n+1} = j \mid J_n = i)$ is the transition kernel of the EMC (J_n) , and $F_{ij}(t) := \mathbb{P}(X_{n+1} \leq t \mid J_n = i, J_{n+1} = j)$ is the conditional distribution function of the sojourn time in the state i given that the next visited state is j , ($j \neq i$). Let us also define the distribution function $H_i(t) := \sum_{j \in E} Q_{ij}(t)$ and its mean value m_i , which is the mean sojourn time of Z in state i . In general, Q_{ij} is a subdistribution, that is, $Q_{ij}(\infty) \leq 1$, hence H_i is a distribution function, $H_i(\infty) = 1$, and $Q_{ij}(0-) = H_i(0-) = 0$.

A special case of SMPs is the one where $F_{ij}(\cdot)$ does not depend on j , that is, $F_{ij}(t) \equiv F_i(t) \equiv H_i(t)$, and

$$Q_{ij}(t) = P(i, j)F_i(t). \quad (2)$$

Any general SMP can be transformed into one of the form Equation (2), (see, e.g., Ref. 13).

Let $\phi(i, t)$, $i \in E, t \geq 0$, be a real-valued measurable function and define the convolution of ϕ by Q as follows:

$$Q * \phi(i, t) := \sum_{k \in E} \int_0^t Q_{ik}(ds) \phi(k, t-s). \quad (3)$$

Now, consider the n -fold convolution of Q by itself. For any $i, j \in E$,

$$Q_{ij}^{(n)}(t) = \begin{cases} \sum_{k \in E} \int_0^t Q_{ik}(ds) Q_{kj}^{(n-1)}(t-s) & n \geq 2 \\ Q_{ij}(t) & n = 1 \\ \delta_{ij} \mathbf{1}_{\{t \geq 0\}} & n = 0, \end{cases}$$

where $\delta_{ij} = 1$, if $i = j$ and $= 0$ otherwise.

It is easy to prove (e.g., by induction) the following fundamental equality:

$$Q_{ij}^{(n)}(t) = \mathbb{P}_i(J_n = j, S_n \leq t). \quad (4)$$

Here, as usual, $\mathbb{P}_i(\cdot)$ means $\mathbb{P}(\cdot \mid J_0 = i)$, and $\mathbb{E}_i$ is the corresponding expectation.

Let us define the Markov renewal function $\psi_{ij}(t)$, $i, j \in E, t \geq 0$, by

$$\begin{aligned} \psi_{ij}(t) &:= \mathbb{E}_i[N_j^*(t)] = \mathbb{E}_i \sum_{n=0}^{\infty} \mathbf{1}_{\{J_n = j, S_n \leq t\}} \\ &= \sum_{n=0}^{\infty} \mathbb{P}_i(J_n = j, S_n \leq t) = \sum_{n=0}^{\infty} Q_{ij}^{(n)}(t). \end{aligned} \quad (5)$$

Another important function is the semi-Markov transition function

$$P_{ij}(t) := \mathbb{P}(Z_t = j \mid Z_0 = i), \quad i, j \in E, t \geq 0,$$

which is the conditional marginal law of the process. We will study this function in the next section.

Definition 2. The SMP Z is said to be regular if

$$\mathbb{P}_i(N(t) < \infty) = 1,$$

for any $t \geq 0$ and any $i \in E$.

For regular SMPs we have $S_n < S_{n+1}$, for any $n \in \mathbb{N}$, and $S_n \rightarrow \infty$. In the sequel, we are concerned with regular SMPs. The following theorem gives two criteria for regularity:

Theorem 1. A SMP is regular if one of the following conditions is satisfied:

1. for every sequence $(j_0, j_1, \dots) \in E^\infty$ and every $C > 0$, at least one of the series

$$\sum_{k \geq 0} [1 - F_{j_k j_{k+1}}(C)], \quad \sum_{k \geq 0} \int_0^C t F_{j_k j_{k+1}}(dt),$$

diverges [2];

2. there exist constants, say $\alpha > 0$ and $\beta > 0$, such that $H_i(\alpha) < 1 - \beta$, for all $i \in E$ [16].

Let us now discuss the nature of different states of an MRP. An MRP is irreducible, if, and only if, its EMC (J_n) is irreducible. A

state i is recurrent (transient) in the MRP, if, and only if, it is recurrent (transient) in the EMC. For an irreducible finite MRP, a state i is positive recurrent in the MRP, if, and only if, it is recurrent in the EMC and if for all $j \in E$, $m_j < \infty$. If the EMC of an MRP is irreducible and recurrent, then all the states are positive recurrent, if, and only if, $m := \nu m := \sum_i v_i m_i < \infty$, and null recurrent, if, and only if, $m = \infty$ (where ν is the stationary probability of EMC (J_n)). A state i is said to be *periodic* with period $a > 0$ if $G_{ii}(\cdot)$ (the distribution function of the random variable $S_2^i - S_1^i$) is discrete concentrated on $\{ka : k \in \mathbb{N}\}$. Such a distribution is also said to be *periodic*. In the opposite case, it is called *aperiodic*. Note that the term *period* has a completely different meaning from the corresponding one of the classic Markov chain theory.

MARKOV RENEWAL THEORY

As the renewal equation in the case of the renewal process theory on the half-real line, the MRE is a basic tool in the theory of SMPs.

Let us write the Markov renewal function given by Equation (5) in matrix form

$$\psi(t) = (I(t) - Q(t))^{(-1)} = \sum_{n=0}^{\infty} Q^{(n)}(t). \quad (6)$$

This can also be written as

$$\psi(t) = I(t) + Q * \psi(t), \quad (7)$$

where $I(t) = I$ (the identity matrix), if $t \geq 0$ and $I(t) = 0$, if $t < 0$.

Equation (7) is a special case of what is called a *Markov renewal equation* (MRE). A general MRE is as follows:

$$\Theta(t) = L(t) + Q * \Theta(t), \quad (8)$$

where $\Theta(t) = (\Theta_{ij}(t))_{i,j \in E}$, $L(t) = (L_{ij}(t))_{i,j \in E}$ are matrix-valued measurable functions, with $\Theta_{ij}(t) = L_{ij}(t) = 0$ for $t < 0$. The function $L(t)$ is a given matrix-valued function and $\Theta(t)$ is an unknown matrix-valued function. We may also consider a vector version of

Equation (8), that is, consider corresponding columns of the matrices Θ and L .

Let $\mathbf{B}$ be the space of all locally bounded, on $\mathbb{R}_+$, matrix functions $\Theta(t)$, that is, $\|\Theta(t)\| = \sup_{i,j} |\Theta_{ij}(t)|$ is bounded on sets $[0, \xi]$, for every $\xi \in \mathbb{R}_+$. Also, denote by $\bar{H}_i(t) := 1 - H_i(t)$.

Theorem 2. (Markov Renewal Theorem [17]). *Let the following conditions be fulfilled:*

1. *The EMC (J_n) is ergodic, that is, irreducible and positive recurrent, with stationary probability $\nu = (\nu_i, i \in E)$.*
2. *The mean sojourn time in every state is finite, i.e. that is, for every $i \in E$,*

$$m_i := \int_0^{\infty} \bar{H}_i(t) dt < \infty, \text{ and}$$

$$m := \sum_{i \in E} \nu_i m_i > 0.$$

3. *The distribution functions $H_i(t)$, $i \in E$, are nonperiodic.*
4. *The functions $L_{ij}(t)$, $t \geq 0$, are direct Riemann integrable, that is, they satisfy the following two conditions, for any $i, j \in E$:*

$$\sum_{n \geq 0} \sup_{n \leq t \leq n+1} L_{ij}(t) < \infty,$$

and

$$\lim_{\Delta \downarrow 0} \left\{ \Delta \sum_{n \geq 0} \left[\sup_{n\Delta \leq t \leq (n+1)\Delta} L_{ij}(t) - \inf_{n\Delta \leq t \leq (n+1)\Delta} L_{ij}(t) \right] \right\} = 0.$$

*Then Equation (8) has a unique solution $\Theta = \psi * L(t)$ belonging to $\mathbf{B}$, and*

$$\lim_{t \rightarrow \infty} \Theta_{ij}(t) = \frac{1}{m} \sum_{\ell \in E} \nu_{\ell} \int_0^{\infty} L_{\ell j}(t) dt. \quad (9)$$

The following result is an important application of the above theorem.

Proposition 1. *The transition function $P(t) = (P_{ij}(t))$ satisfies the following MRE*

$$P(t) = I(t) - H(t) + Q * P(t),$$

which, under conditions (1)–(3) of Theorem 2, has the unique solution

$$P(t) = \psi * (I(t) - H(t)), \quad (10)$$

and, for any $i, j \in E$,

$$\lim_{t \rightarrow \infty} P_{ji}(t) = v_i m_i / m =: \pi_i. \quad (11)$$

Here $H(t) = \text{diag}(H_i(t))$ is a diagonal matrix.

It is worth noticing that, in general, the stationary distribution π of the SMP Z is not equal to the stationary distribution v of the EMC (J_n) . Nevertheless, we have $\pi = v$ when, for example, m_i is independent of $i \in E$.

STATISTICAL INFERENCE

Statistical inference for SMPs is provided in several papers. Moore and Pyke [18] studied empirical estimators for finite semi-Markov kernels; Lagakos *et al.* [19] gave maximum likelihood estimators for nonergodic finite semi-Markov kernels; Akritas and Roussas [20] gave parametric local asymptotic normality results for SMPs; Gill [21] studied Kaplan–Meier type estimators by point process theory; Greenwood and Wefelmeyer [22] studied efficiency of empirical estimators for linear functionals in the case of a general state space; Ouhbi and Limnios [23] studied nonparametric estimators of semi-Markov kernels, nonlinear functionals of semi-Markov kernels, including Markov renewal matrices and reliability functions [15], and rate of occurrence of failure functions [24]. Also see Ref. 25. We will give here some elements of the nonparametric estimation of semi-Markov kernels.

Let us consider an observation of an irreducible SMP Z , with finite state space E , up to a fixed time T , that is, $(Z_s, 0 \leq s \leq T) \equiv (J_0, J_1, \dots, J_{N(T)}; X_1, \dots, X_{N(T)-1}, T - S_{N(T)})$, if $N(T) > 0$ and $(Z_s, 0 \leq s \leq T) \equiv (J_0)$, if $N(T) = 0$.

The empirical estimator $\hat{Q}_{ij}(t, T)$ of $Q_{ij}(t)$ is defined by

$$\hat{Q}_{ij}(t, T) = \frac{1}{N_i(T)} \sum_{k=1}^{N(T)} \mathbf{1}_{\{J_{k-1}=i, J_k=j, X_k \leq t\}}. \quad (12)$$

Then we have the following result from Moore and Pyke [18]; see also Ref. 23. We denote by $\xrightarrow{a.s.}$ and $\xrightarrow{d}$ the almost sure convergence and convergence in distribution, respectively. Denote by $N(a, b)$ the normal random variable with mean a and variance b .

Theorem 3. *For any fixed $i, j \in E$, as $T \rightarrow \infty$, we have*

1. (Strong consistency) $\max_{i,j} \sup_{t \in (0, T)} |\hat{Q}_{ij}(t, T) - Q_{ij}(t)| \xrightarrow{a.s.} 0$,
2. (Asymptotic normality) $T^{1/2}(\hat{Q}_{ij}(t, T) - Q_{ij}(t)) \xrightarrow{d} N(0, \sigma_{ij}^2(t))$,
where $\sigma_{ij}^2(t) := \mu_{ii} Q_{ij}(t)[1 - Q_{ij}(t)]$.

We define estimators of the Markov renewal function and of transition probabilities by a plug-in procedure, that is, replacing the semi-Markov kernel $Q_{ij}(t)$ in Equations (6) and (10) by the empirical estimator kernel $\hat{Q}_{ij}(t, T)$.

The following two results concerning the Markov renewal function estimator, $\hat{\psi}_{ij}(t, T)$, and the transition probability function estimator, $\hat{P}_{ij}(t, T)$, of Z were proved by Ouhbi and Limnios [23].

Theorem 4. [23]. *The estimator $\hat{\psi}_{ij}(t, T)$ of the Markov renewal function $\psi_{ij}(t)$ satisfies the following two properties:*

1. (Strong consistency) *it is uniformly strongly consistent, that is, as $T \rightarrow \infty$,*

$$\max_{i,j} \sup_{t \in (0, T)} |\hat{\psi}_{ij}(t, T) - \psi_{ij}(t)| \xrightarrow{a.s.} 0.$$

2. (Asymptotic normality) *For any fixed $t > 0$, it converges in distribution, as $T \rightarrow \infty$, to a normal random variable, that is,*

$$T^{1/2}(\hat{\psi}_{ij}(t, T) - \psi_{ij}(t)) \xrightarrow{d} N(0, \sigma_{ij}^2(t)),$$

where $\sigma_{ij}^2(t) = \sum_{r \in E} \sum_{k \in E} \mu_{rr} \{(\psi_{ir} * \psi_{kj})^2 * Q_{rk} - (\psi_{ir} * \psi_{kj} * Q_{rk})^2\}(t)$.

Theorem 5. [23]. *The estimator $\hat{P}_{ij}(t, T)$ of the transition function $P_{ij}(t)$, satisfies the following two properties:*

1. (Strong consistency) for any fixed $L > 0$, we have, as $T \rightarrow \infty$

$$\max_{i,j} \sup_{t \in [0,L]} \hat{P}_{ij}(t, T) - P_{ij}(t) \xrightarrow{a.s.} 0.$$

2. (Asymptotic normality) For any fixed $t > 0$, we have, as $T \rightarrow \infty$,

$$T^{1/2}(\hat{P}_{ij}(t, T) - P_{ij}(t)) \xrightarrow{d} N(0, \sigma_{ij}^2(t)),$$

where

$$\begin{aligned} \sigma_{ij}^2(t) = & \sum_{r \in E} \sum_{k \in E} \mu_{rr} \\ & \times [(1 - H_i) * B_{irkj} - \psi_{ij} \mathbf{1}_{\{r=j\}}]^2 \\ & * Q_{rk}(t) - [((1 - H_i) * B_{irkj} - \psi_{ij} \mathbf{1}_{\{r=j\}}) \\ & * Q_{rk}(t)]^2, \end{aligned}$$

and

$$B_{irkj}(t) = \sum_{n=1}^{\infty} \sum_{\ell=1}^n Q_{ir}^{(\ell-1)} * Q_{kj}^{(n-\ell)}(t).$$

RELIABILITY OF SEMI-MARKOV SYSTEMS

For a stochastic system with state space E described by a SMP (Z_t) , let us consider a partition U, D of E , that is, $E = U \cup D$, with $U \cap D = \emptyset$, $U \neq \emptyset$, and $D \neq \emptyset$. The set U contains the up states and D contains the down states of the system. The reliability is defined by $R(t) := \mathbb{P}(Z_s \in U, \forall s \in [0, t])$. If we define the conditional reliability by $R_i(t) := \mathbb{P}(Z_s \in U, \forall s \in [0, t] \mid Z_0 = i)$, then for any initial distribution law vector α , we have $R(t) := \sum_{i \in U} \alpha_i R_i(t)$. For the finite state space case, without loss of generality, let us enumerate first the up states and next the down states, that is, for $E = \{1, 2, \dots, d\}$, we have $U = \{1, \dots, r\}$ and $D = \{r+1, \dots, d\}$.

The conditional reliability $R_i(t)$ $i \in U$ fulfills the following MRE:

$$R_i(t) = \bar{H}_i(t) + \sum_{j \in U} \int_0^t Q_{ij}(ds) R_j(t-s), \quad (13)$$

which has the following solution

$$R_i(t) = \sum_{j \in U} (\psi_{ij} * \bar{H}_j)(t). \quad (14)$$

Integrating Equation (13) over $[0, \infty)$, we get

$$\begin{aligned} & (MTTF_1, \dots, MTTF_r)' \\ &= (I - P_{11})^{-1} (m_1, \dots, m_r)', \end{aligned} \quad (15)$$

where $MTTF_j$ is the mean time to failure starting from the state $j \in E$, and C' denotes the transpose of the vector or the matrix C .

The above reliability indicators and some additional ones are formulated in matrix form and are given in the following table.

Notation. In Table 1, we have $\bar{\mathbf{H}}_1(t) = (\bar{H}_i(t); i \in U)'$, $\bar{\mathbf{H}}_2(t) = (\bar{H}_i(t); i \in D)'$, $\bar{\mathbf{H}}_{10}(t) = (\bar{H}_{10}(t); i \in U; 0, \dots, 0)'$, $\mathbf{m}_1 = (m_i; i \in U)'$, $\mathbf{m}_2 = (m_i; i \in D)'$, $\mathbf{1}_r = (1, \dots, 1)'$ r -ones. All of the above vectors are column vectors. Furthermore, index 1 means restriction of the corresponding vector or matrix on U and index 2 means restriction of the corresponding vector or matrix on D , that is, $Q_{11}(t)$, means restriction of the matrix $Q(t)$ on $U \times U$ and α_1 restriction of the row vector α on U . By $A^{(-1)}(t)$ we mean the inverse of the matrix A in the convolution sense (see

Table 1. Closed Form Solution for Reliability and Related Measurements

Reliability	$R(t) = \alpha_1 (\mathbf{I} - \mathbf{Q}_{11})^{(-1)} * \bar{\mathbf{H}}_1(t)$
Availability	$A(t) = \alpha (\mathbf{I} - \mathbf{Q})^{(-1)} * \bar{\mathbf{H}}_{10}(t)$
Maintainability	$M(t) = 1 - \alpha_2 (\mathbf{I} - \mathbf{Q}_{22})^{(-1)} * \bar{\mathbf{H}}_2(t)$
Mean time to failure	$MTTF = \alpha_1 (\mathbf{I} - \mathbf{P}_{11})^{-1} \mathbf{m}_1$
Mean time to repair	$MTTR = \alpha_2 (\mathbf{I} - \mathbf{P}_{22})^{-1} \mathbf{m}_2$
Mean up time	$MUT = \frac{\nu_1 \mathbf{m}_1}{\nu_2 \mathbf{P}_{21} \mathbf{1}_r}$
Mean down time	$MDT = \frac{\nu_2 \mathbf{m}_2}{\nu_1 \mathbf{P}_{12} \mathbf{1}_{d-r}}$

Ref. 13). For example, if

$$A(t) = \begin{pmatrix} a(t) & b(t) \\ c(t) & d(t) \end{pmatrix}, \text{ then} \\ A^{(-1)}(t) = (a * d(t) - b * c(t))^{(-1)} \\ * \begin{pmatrix} d(t) & -b(t) \\ -c(t) & a(t) \end{pmatrix}.$$

Reliability estimation. From the estimator given by Equation (12), the following plug-in estimator of reliability is proposed:

$$\widehat{R}(t, T) = \widehat{\alpha}_1(\mathbf{I} - \widehat{\mathbf{Q}}_{11})^{(-1)} * \widehat{\mathbf{H}}_1(t, T).$$

The following properties are fulfilled by the above reliability estimator:

Theorem 6. [15]. *For any fixed $t > 0$ and for any $L \in (0, \infty)$, we have*

1. (Strong consistency)

$$\sup_{0 \leq t \leq L} |\widehat{R}(t, T) - R(t)| \xrightarrow{a.s.} 0, \\ \text{as } T \rightarrow \infty,$$

2. (Asymptotic normality)

$$T^{1/2}(\widehat{R}(t, T) - R(t)) \xrightarrow{d} N(0, \sigma_R^2(t)), \\ \text{as } T \rightarrow \infty,$$

where

$$\sigma_R^2(t) \\ = \sum_{i \in U} \sum_{j \in E} \mu_{ii} \left\{ \left(B_{ij} \mathbf{1}_{\{j \in U\}} - \sum_{r \in U} \alpha(r) \psi_{ri} \right)^2 \right. \\ * Q_{ij}(t) - \left[\left(B_{ij} \mathbf{1}_{\{j \in U\}} - \sum_{r \in U} \alpha(r) \psi_{ri} \right) \right. \\ \left. * Q_{ij}(t) \right]^2 \left. \right\}$$

and

$$B_{ij}(t) = \sum_{n \in E} \sum_{k \in U} \alpha(i) \psi_{ni} * \psi_{jk} * (I - H_k(t)).$$

For further results on estimation, see Refs 15, 23, 24, 26, 27.

SEMI-MARKOV CHAINS AND HIDDEN MODELS

In this section, we present semi-Markov chains (SMC), which are semi-Markov processes in discrete-time, and hidden semi-Markov models (HSMM).

Let us consider the MRP $(J_n, S_n)_{n \in \mathbb{N}}$ in discrete time $k \in \mathbb{N}$, with state space the countable set E . The semi-Markov kernel q is defined by

$$q_{ij}(k) := \mathbb{P}(J_{n+1} = j, S_{n+1} - S_n = k \mid J_n = i), \\ \text{with } i, j \in E, \quad k, n \in \mathbb{N}. \quad (16)$$

Define also $q_{ij}(K) = \sum_{k \in K} q_{ij}(k)$, where $K \subset \mathbb{N}$. So, as in the continuous-time case, an SMC is determined by its semi-Markov kernel q and its initial distribution law α .

The process (J_n) is the EMC of the MRP (J_n, S_n) with transition kernel $P = (P(i, j))$. The semi-Markov kernel q is written as

$$q_{ij}(k) = P(i, j) f_{ij}(k),$$

where $f_{ij}(k) := \mathbb{P}(S_{n+1} - S_n = k \mid J_n = i, J_{n+1} = j)$, is the conditional distribution of the sojourn time in the state i given that the next visited state is j , ($j \neq i$).

Define the counting process of jumps $N(k) := \max\{n \geq 0 : S_n \leq k\}$. The SMC is defined as follows:

$$Z_k = J_{N(k)}, \quad k \in \mathbb{N}. \quad (17)$$

When $q_{ij}(k) = p_{ij}(p_{ii})^{k-1}$, $k = 1, 2, \dots$, for all $i, j \in E$, $i \neq j$, then the SMC Z is a Markov chain with transition matrix $p = (p_{ij})$. In this case, the transition matrix of the EMC is $P(i, j) = p_{ij}/(1 - p_{ii})$, if $p_{ii} < 1$ and $i \neq j$, and $P(i, j) = 0$, if $i = j$ or $p_{ii} = 1$, and the conditional transition function is $f_{ij}(k) = (1 - p_{ii})(p_{ii})^{k-1}$.

The Markov renewal function ψ is defined by

$$\psi_{ij}(k) := \sum_{n=0}^k q_{ij}^{(n)}(k). \quad (18)$$

The general MRE in the discrete case is as follows:

$$\Theta(k) = L(k) + q * \Theta(k),$$

where $\Theta(k), k \in \mathbb{N}$, is an unknown sequence of real matrices (of finite or of infinite dimension), $L(k), k \in \mathbb{N}$, is a known sequence of real matrices, and $q(k), k \in \mathbb{N}$, a semi-Markov kernel. The convolution in discrete time is $(q * \Theta)_{ij}(k) = \sum_{\ell \in E} \sum_{s=0}^k q_{i\ell}(s) \Theta_{\ell j}(k-s)$. The general solution of the above MRE is given by

$$\Theta(k) = \psi * L(k).$$

For example, the transition probabilities of the SMC $Z, P_{ij}(k)$, satisfy the following MRE in matrix form:

$$P(k) = I - H(k) + q * P(k),$$

where its unique solution is

$$P(k) = \psi * (I - H)(k).$$

The reliability indicators are given by the same formulae as in the continuous-time case, in Table 1, only replacing Q by q and the step function $I = I(t)$, by the Dirac matrix measure $I\delta$ at the origin (see Ref. 14). Estimation results for discrete-time SMCs can be found in Ref. 14.

An HSMM is defined by a bivariate process (Z_k, Y_k) , where Z_k is an E -valued SMC (unobserved) and Y_k is an A -valued process (observed) depending on Z_k . We suppose here that E and A are countable sets. This dependence structure in the HSMM is given by the following relation:

$$\begin{aligned} \mathbb{P}(Z_{k+1} = j, Y_{k+1} = l \mid Z_s, Y_s; s \in \{0, 1, \dots, k\}) \\ = \mathbb{P}(Z_{k+1} = j \mid Z_k, U_k) \\ \times \mathbb{P}(Y_{k+1} = l \mid Z_{k+1} = j), \end{aligned}$$

where $U_k = k - S_{N(k)}$. This is an SM-M0 type HSMM. A more general type is the SM-Mm HSMM, which satisfies the following relation:

$$\begin{aligned} \mathbb{P}(Z_{k+1} = j, Y_{k+1} = l \mid Z_s, Y_s; s \in \{0, 1, \dots, k\}) \\ = \mathbb{P}(Z_{k+1} = j \mid Z_k, U_k) \\ \times \mathbb{P}(Y_{k+1} = l \mid Z_{k+1} = j, Y_k, \dots, Y_{k-m+1}). \end{aligned}$$

The main goal here is to estimate the semi-Markov kernel and, of course,

the conditional distributions of Y , by observing only Y over $[0, M]$, that is, $(Y_0^M = y_0^M) \equiv (Y_0 = y_0, Y_1 = y_1, \dots, Y_M = y_M)$, where $(y_0, y_1, \dots, y_M) \in A^{M+1}$. The quantities to be estimated here are $\theta = (q, \Gamma)$, where q is the semi-Markov kernel, and Γ the conditional distribution of Y , that is, $\Gamma(i, l) = \mathbb{P}(Y_k = l \mid Z_k = i)$ for any $k \in \mathbb{N}, i \in E, l \in A$.

The likelihood function for the complete data set is

$$\begin{aligned} L_M(\theta; Z_0^M, Y_0^M) \\ = \alpha(Z_0) \prod_{n=1}^{N(M)} q(J_{n-1}, J_n, X_n) \bar{H}(J_{N(M)}, U_M) \\ \times \prod_{k=0}^M \Gamma(Z_k, Y_k). \end{aligned}$$

Here, for convenience, we used the notation $q(i, j, k)$ instead of $q_{ij}(k)$ for all functions.

The maximum likelihood estimators can be obtained by an algorithm for incomplete data such as expectation maximization (EM) or stochastic EM. In fact, instead of maximizing the likelihood of the observed data, that is, $L_M^0(\theta; Y_0^M) = \sum_{Z_0^M \in E^{M+1}} L_M(\theta; Z_0^M, Y_0^M)$, one maximizes the conditional expectation over θ ,

$$\mathbb{E}_{\theta^{(m)}} \left[\log L_M(\theta; Z_0^M, Y_0^M) \mid Y_0^M \right]$$

in order to obtain $\theta^{(m+1)}$, and so on. Under appropriate general conditions the sequence $\theta^{(m)}, m \geq 0$, converges to the true value of the parameter θ .

For a given system whose the temporary behavior is described by an SMC, say Z , and the values of some indicators, that is, noise, temperature, pressure, and so on, are observed, say Y , we would like to estimate the state of the system in a given present time or into the future by observing Y only. This is a typical hidden semi-Markov problem.

CONCLUDING REMARKS

Several topics concerning SMP have been omitted. For example, results on time-nonhomogeneous SMP can be found in

Refs 28–30; SM decision processes in Refs 16, 31; calculation and numerical aspects [13,29,32]; limit theorems and convergence of SMP in series scheme in Refs 8–10, 33–37; stochastic approximations in Refs 9, 10; (stochastic) additive functionals in Refs 9, 10, 13; diffusion type SMP in Ref. 38; entropy of SMP [39], and so on; and also some important applications, such as reliability and maintenance theory in Refs 13–15, 24, 40–43; queueing theory in Refs 44, 45; insurance and finance in Refs 10, 29, 46; words occurrences in Ref. 47; estimation in discrete time in Refs 14, 48; phase-type distributions in Refs 13, 43, 45, and so on. Several chapters in Refs 28 and 29 concern the above aspects. For a detailed presentation of SMCs and HSMMs see Ref. 14.

SEMI-MARKOV PROCESSES

YASEMIN SERIN

INTRODUCTION

A semi-Markov process (SMP) is continuous-time countable state space process that is a generalization of continuous-time Markov chains in the way that the sojourn times come from general distributions. The Markovian property holds only at the transition points. Relaxing the exponential sojourn time assumption broadens the field of application of the results. For example, M/G/1 and G/M/1 queues can be modeled as SMPs and transient and limiting behavior can be analyzed using the results summarized below. This article benefitted from Refs 1–3 and is largely based on Ref. 4. The proofs of all the following theorems can be found in Ref. 4.

DEFINITIONS AND TRANSIENT BEHAVIOR

In a continuous-time Markov chain, states of a discrete-time Markov chain (DTMC) are visited with exponentially distributed sojourn times. An SMP is a generalization where sojourn times have a general distribution. So, an SMP enters a state, stays in that state for a random amount of time, and jumps into some state according to a Markov transition probability; therefore, the Markovian property holds only at the transition points. A formal definition is given next.

Let $\{X_n, n = 0, 1, 2, \dots\}$ be a discrete-time stochastic process with a countable state space S . Let Y_n be a sequence of random variables taking values on the nonnegative real line, $S_n = \sum_{k=1}^n Y_k$ and $N(t) = \max\{n : S_n \leq t\}$.

Definition 1. The continuous-time process $\{X(t), t \geq 0\}$ defined by $X(t) = X_{N(t)}$ is called a *semi-Markov process* (SMP) if the sequence $\{(X_n, Y_{n+1}), n = 0, 1, \dots\}$ satisfies

$$\begin{aligned} P(X_{n+1} = j, Y_{n+1} < y | X_n = i, Y_n, X_{n-1}, \\ Y_{n-1}, \dots, X_1, Y_1, X_0) \\ = P(X_{n+1} = j, Y_{n+1} < y | X_n = i) \\ = G_{ij}(y) \end{aligned}$$

for all $i, j \in S, n = 0, 1, \dots$ and $y \geq 0$.

The SMP stays in state X_n for Y_{n+1} units of time and jumps to X_{n+1} at time S_{n+1} . Here, $N(t)$ represents the number of transitions up to time t . Independence of G from n implies time homogeneity of the process. It must be noted that with this definition, unlike continuous-time Markov chains, a transition from a state to itself is allowed for SMPs. The matrix defined by

$$G = [G_{ij}(y)]_{i,j \in S}$$

is called the *kernel of the SMP*. Together with an initial distribution, the kernel completely describes the SMP. The cdf of the sojourn time in state i is

$$\begin{aligned} F_i(y) &= P(Y_1 < y | X_0 = i) \\ &= \sum_{j \in S} G_{ij}(y). \end{aligned}$$

The transition probability of the DTMC $\{X_n, n = 0, 1, 2, \dots\}$, that is *the embedded DTMC* is $p_{ij} = G_{ij}(\infty)$. Here, it will be assumed that finite number of transitions can occur in a finite time; that is $F_i(\infty) = 1$ for all $i \in S$. This regularity definition holds for finite state SMPs.

Example. A Series System. Consider an equipment with N components. The equipment works as long as all the components work. Component i works for an

exponential(λ_i) units of time and its repair takes R_i units of time with cdf $F_i(r)$ and mean r_i . There is a single repairman and components do not fail when one is being repaired. Failure of a component or a repair completion define a transition time. Then the process defined by

$$X_n = \begin{cases} i, & \text{if component } i \text{ fails at the } n\text{th transition} \\ 0, & \text{if a repair is over at the } n\text{th transition} \end{cases}$$

is a DTMC and the process $\{X(t), t \geq 0\}$ defined by

$$X(t) = \begin{cases} i, & \text{if component } i \text{ is being repaired at time } t \\ 0, & \text{if all components are working at time } t \end{cases}$$

with $S = \{0, 1, 2, \dots, N\}$ is an SMP with kernel G where for $i = 1, 2, \dots, N$, and $y \geq 0$,

$$G_{0i}(y) = \frac{\lambda_i}{\sum_{j=1}^N \lambda_j} \left(1 - e^{-y \sum_{j=1}^N \lambda_j} \right),$$

$$G_{i0}(y) = F_i(y),$$

$$G_{ij}(y) = 0, \text{ otherwise.}$$

The transition probabilities of the embedded DTMC are, for $i = 1, 2, \dots, N$,

$$p_{0i} = \frac{\lambda_i}{\sum_{j=1}^N \lambda_j},$$

$$p_{i0} = 1,$$

$$p_{ij} = 0, \text{ otherwise.}$$

The state transition probabilities $p_{ij}(t) = P(X(t) = j | X(0) = i)$ of the SMP for $i, j \in S$ and finite t represent the transient behavior of the process. They can be obtained as in the following theorem.

Theorem 1. *The transition probabilities of an SMP satisfies the following Markov renewal type equation*

$$p_{ij}(t) = \int_0^t \sum_{k \in S} p_{kj}(t-u) dG_{ik}(u) + \int_t^\infty \sum_{k \in S} \delta_{ij} dG_{ik}(u)$$

and the solution is

$$p_{ij}(t) = \delta_{ij}(1 - F_i(t)) + \int_0^t (1 - F_i(t-u)) dM_{ij}(u),$$

where $M_{ij}(t) = \sum_{n=1}^\infty G_{ij}^{(n)}(t)$ and $A^{(n)}$ is n -fold convolution of A and $\delta_{ij} = 1$ if $i = j$ and 0, otherwise.

STATE CLASSIFICATION AND LIMITING PROBABILITIES

The behavior of an SMP, in the long run (as t goes to ∞), can be analyzed in two parts: first, the probability of finding the process in a particular state in the long run should be investigated. Next, since the sojourn times are not memoryless, the cdf of the time until the next transition in the long run should also be investigated.

For the state classification, the states that behave in the same way are identified and the limiting probabilities are given. The *first passage time from state i to state j* is

$$T_{ij} = \min\{t \geq Y_1 : X(t-) \neq j, X(t) = j | X(0) = i\}.$$

Here, $t-$ represents the time point just before t . Let the expected time spent in i before a transition be $\mu_i = E[Y_1 | X(0) = i]$ and the expected first passage time from i to j be $\mu_{ij} = E[T_{ij}]$ for $i, j \in S$. Generally, μ_i is determined by the given sojourn time distributions. The expected first passage times can be computed as in the following theorem.

Theorem 2. *The expected first passage times satisfy the following system of linear equations:*

$$\mu_{ij} = \mu_i + \sum_{k \neq j, k \in S} p_{ik} \mu_{kj} \text{ for } i, j \in S.$$

Example. A Series System (continued). From Theorem 2, the expected first

passage times for the series system example are, for $i = 1, 2, \dots, N$,

$$\begin{aligned}\mu_{i0} &= r_i, \\ \mu_{00} &= \frac{1 + \sum_{k=1}^N r_k \lambda_k}{\sum_{k=1}^N \lambda_k}, \\ \mu_{0i} &= \frac{1 + \sum_{k=1, k \neq i}^N r_k \lambda_k}{\lambda_i}, \\ \mu_{ij} &= r_i + \frac{1 + \sum_{k=1, k \neq j}^N r_k \lambda_k}{\lambda_j}, \\ &\text{for } j = 1, 2, \dots, N.\end{aligned}$$

The usual definitions of recurrence/transience, aperiodicity, and irreducibility apply to SMPs.

Definition. A state of the SMP is recurrent (transient) if it is recurrent (transient) in the embedded DTMC.

Definition. A recurrent state i of the SMP is positive recurrent if $\mu_{ii} < \infty$ and it is null recurrent if $\mu_{ii} = \infty$.

Definition. An SMP is irreducible if the embedded DTMC is irreducible.

Definition. A state i of the SMP is aperiodic if the T_{ii} is aperiodic.

The states in an irreducible subset of S have the same classifications; these properties are class properties. Therefore, it is sufficient to study the limiting behavior of the irreducible SMPs. Let $P = [p_{ij}]$. The following theorem relates the stationary distribution of the embedded DTMC with the expected first passage times and the limiting distribution of the SMP.

Theorem 3. Let $\{X(t), t \geq 0\}$ be an irreducible SMP and let π be a positive solution to $\pi = \pi P$. If the SMP is recurrent then

$$\mu_{jj} = \frac{\sum_{i \in S} \pi_i \mu_i}{\pi_j}.$$

If the SMP is positive recurrent then

$$\lim_{t \rightarrow \infty} p_{ij}(t) = \frac{\pi_j \mu_j}{\sum_{k \in S} \pi_k \mu_k}.$$

Example. A Series System (continued). The limiting probabilities of the embedded DTMC are

$$\begin{aligned}\pi_0 &= \frac{1}{2}, \\ \pi_i &= \frac{\lambda_i}{2 \sum_{k=1}^N \lambda_k} \quad \text{for } j = 1, 2, \dots, N.\end{aligned}$$

The probability that the series system is working in the long run is

$$\lim_{t \rightarrow \infty} p_{i0}(t) = \frac{1}{1 + \sum_{k=1}^N r_k \lambda_k}$$

and the probability that the component i is under repair in the long run is

$$\lim_{t \rightarrow \infty} p_{ij}(t) = \frac{r_j \lambda_j}{1 + \sum_{i=1}^N r_k \lambda_k}$$

Finally, the limiting distribution of the time until the next transition is given. Keep in mind that $S_{N(t)+1}$ is the time of the first transition after t and $S_{N(t)+1} - t$ is the remaining time until the next transition.

Theorem 4. Let $\{X(t), t \geq 0\}$ be an irreducible positive recurrent and aperiodic SMP. Then

- (i) $\lim_{t \rightarrow \infty} P(X(t) = i, S_{N(t)+1} > t + x, X_{N(t)+1} = j | X(0) = k) = \frac{p_i}{\mu_i}, \int_x^\infty (p_{ij} - G_{ij}(y)) dy$
- (ii) $\lim_{t \rightarrow \infty} P(X(t) = i, S_{N(t)+1} > t + x | X(0) = k) = \frac{p_i}{\mu_i} \int_x^\infty (1 - F_i(y)) dy,$
- (iii) $\lim_{t \rightarrow \infty} P(S_{N(t)+1} > t + x | X(t) = i) = \frac{1}{\mu_i} \int_x^\infty (1 - F_i(y)) dy.$

Example. M/G/1 Queue. The arrivals to a queue are according to a Poisson process with rate λ and the iid service times have a general distribution with cdf $B(s)$ with mean $E(S)$ and second moment $E(S^2)$. Let X_n be the number of customers left in the system just after the n th departure, Y_n be the n th service time and $N(t)$ be the number of departures

from the queue in t time units. The process defined by $X(t) = X_{N(t)}$ is an SMP with

$$G_{ij}(y) = \begin{cases} \int_0^x \frac{e^{-\lambda x} (\lambda x)^{j-i+1}}{(j-i+1)!} dB(x), & \text{if } i > 0, \\ \int_0^x \frac{e^{-\lambda x} (\lambda x)^j}{j!} dB(x), & \text{if } i = 0, \\ 0, & \text{otherwise.} \end{cases} \quad j \geq i-1,$$

From Theorem 4, in the long run, the distribution of the remaining service time of the customer in service is

$$\begin{aligned} P(S_{N(t)+1} > t + x | X(t) = j) \\ = \frac{1}{E(S)} \int_x^\infty (1 - B(y)) dy \text{ if } j > 0 \end{aligned}$$

Hence if $j > 0$, the expected remaining service time is

$$\begin{aligned} E(S_{N(t)+1} - t | X(t) = j) \\ = \int_0^\infty \frac{1}{E(S)} \int_x^\infty (1 - B(y)) dy dx \\ = \frac{E(S^2)}{E(S)}. \end{aligned}$$

SENSITIVITY ANALYSIS AND DYNAMIC PROGRAMMING

CHIN HON TAN
JOSEPH C. HARTMAN
Industrial and Systems
Engineering, University of
Florida, Gainesville, Florida

Dynamic programming (DP) has been successfully applied to a wide range of problems in a variety of fields [1–4] since it was proposed by Richard Bellman in the middle of the last century [5]. One of the main advantages of DP lies in its ability to account for the dynamics of a system and it is often used by operations researchers to solve problems involving sequential decisions. In addition, unlike most optimization techniques, DP is able to handle a wide range of cost and/or reward functions. Given its versatility, it is not surprising that DP is used across various disciplines, including artificial intelligence, control, economics, and operations research. However, DP does have its drawbacks as well. The size of a dynamic program grows rapidly with the dimension of the problem. This is commonly referred to as *the curse of dimensionality* and has been the main challenge in applying DP approaches to solving real-world problems. In light of the computational difficulties that arise from the curse of dimensionality, researchers have proposed a variety of approximation approaches, including state aggregation and value function approximation, to solve large dynamic programs. The interested reader is referred to Powell [6] for a detailed presentation of approximate DP.

The validity of any DP solution depends on the accuracy of the model and the data for a given instance. However, the parameters of the model are often uncertain and estimated in practice. Hence, the robustness or stability of the solution with respect to changes in the model parameters is of interest. One approach is to solve the problem

for different parameters and try to infer the relationship between the model parameters and the optimal solution from the resulting solutions [7,8]. However, this approach has two drawbacks. First, when the size of the problem or the number of scenarios to analyze is large, this “brute force” approach can be very time-consuming and may not be feasible in practice. Second, unless the properties regarding the relationship between the model parameters and the optimal solutions are known (e.g., continuous or monotonic), the solution for a set of parameter values may not provide insights on the solution for another set of parameter values. For example, suppose that ρ is some model parameter. One cannot guarantee that the optimal objective value for $\rho = 2$ must be between the optimal objective values for $\rho = 1$ and $\rho = 3$. From a theoretical and practical perspective, more sophisticated approaches for conducting sensitivity analysis in DP models are desired.

In this article, we review the approaches that researchers have proposed for conducting sensitivity analysis in discrete dynamic programs. Broadly speaking, sensitivity analysis is the study of how changes in a model affects the resulting output. In our context, we are interested in the sensitivity of an optimal solution with respect to changes in the model parameters. In addition, we highlight that DP is related to other optimization methodologies. Relevant work in linear programming (LP) and network optimization are discussed.

In sensitivity analysis, we study the stability or robustness of an optimal solution. However, researchers have also proposed finding solutions that are robust to the variations in the model parameters in dynamic programs. Robust DP will not be discussed in this article. Recent papers on robust solution approaches include the work of Givan *et al.* [9], Iyengar [10], Nilim and El Ghaoui [11], and Itoh and Nakamura [12].

Researchers have also pointed out that the model is usually an approximation of the actual problem and hence, the structure of

the model itself is doubtful. Literature that address model uncertainties include the work of Briggs *et al.* [13], Chatfield [14], Draper [15], and Walker and Fox-Rushby [16]. In this article, we limit ourselves to uncertainties in the model parameters.

This article proceeds as follows: In the next section, we present various concepts of sensitivity analysis in the optimization literature. Then, we survey sensitivity analysis approaches and results in discrete dynamic programs. In the section titled “Linear Programming,” we highlight the relationship between DP and LP. In addition, we demonstrate how results from LP can be applied to discrete dynamic programs. We conclude with a summary and highlight directions for future research.

CONCEPTS OF SENSITIVITY ANALYSIS IN OPTIMIZATION

Let S and Π denote the set of states and the set of policies, respectively. Let $A(s)$ denote the set of actions available with $s \in S$. We consider problems of the following form:

$$V^\pi = \sum_{t=0}^T \gamma^t r^\pi(s_t^\pi), \quad (1)$$

where V^π is the value function of the system under policy $\pi \in \Pi$ through the horizon T . T can be either finite or infinite. $s_t^\pi \in S$ is the state of the system at time t under π and $\pi(s) \in A(s)$ is the action that is taken at state s under π . Note that the action that is selected depends solely on the state and is independent of t . This stationary policy assumption is not restrictive since additional states can always be declared to address the dependency of π on t . r^a is the reward associated with action a and γ is the per-period discount factor. If the state transitions are stochastic, s_t^π is random and the value function is expressed as

$$V^\pi = \mathbb{E} \left[\sum_{t=0}^T \gamma^t r^\pi(s_t^\pi) \right]. \quad (2)$$

Let π^* denote an optimal policy and V denote the optimal value function. The objective is

to find a policy that maximizes the value function,

$$V = V^{\pi^*} = \max_{\pi \in \Pi} V^\pi. \quad (3)$$

We are interested in how V and π^* change when model parameters vary. We first consider the case where the variations in the model parameters can be expressed by a single parameter ρ (i.e., univariate). For example, suppose that γ is allowed to vary between 0.85 and 0.95. We model this by setting $\gamma = 0.9 + \rho$, where $\rho \in [-0.05, 0.05]$. This modeling approach allows for dependencies between the model parameters and is particularly useful when modeling simple variations in transition probabilities, where the sum of probabilities must add to one.

Suppose that the problem is solved for $\rho = \rho^{(0)}$ and the optimal value function and optimal policy, $V^{(0)}$ and $\pi^{(0)}$, are obtained. Sensitivity analysis aims to answer one or more of the following questions:

1. What is $\frac{dV^{\pi^{(0)}}}{d\rho} \big|_{\rho=\rho^{(0)}}$?
2. What is the range of ρ values for which $\pi^{(0)}$ is optimal?
3. What is V if $\rho = \rho^{(0)} + \delta$, for some $\delta \in \mathbb{R}$?
4. What is π^* if $\rho = \rho^{(0)} + \delta$, for some $\delta \in \mathbb{R}$?

Questions 1 and 2 are specific to $\pi^{(0)}$ and can only be answered after $\pi^{(0)}$ has been identified. Hence, these questions are addressed in a *posterior analysis* [17] or *postoptimal analysis* [18,19]. The answers to questions 3 and 4 do not require advanced knowledge of $V^{(0)}$ and $\pi^{(0)}$. However, $V^{(0)}$ and $\pi^{(0)}$ can often be used to obtain or approximate V and π^* (see the section titled “Dynamic Programming”) and knowledge of $V^{(0)}$ and $\pi^{(0)}$ may provide insights to the answers of questions 3 and 4.

Besides posterior analysis, researchers have also considered *prior analysis* where knowledge of $V^{(0)}$ and $\pi^{(0)}$ is not required. For example, inverse parametric optimization aims to find the ρ value where a policy is optimal or good [20–22]). Prior analysis will

not be discussed in this article but the interested reader is referred to Fernandez-Baca and Venkatachalam [17] for a discussion on this topic.

Alternatively, the analysis can also be classified as being either *local* or *global* [23]. Question 1 takes a local perspective and is concerned with changes in the ε -neighborhood of $\rho^{(0)}$. Wagner [24] considers question 2 to be local as well since it is concerned with the properties of $\pi^{(0)}$. In contrast, questions 3 and 4 explore the variations across a wider range of ρ values and possibly different π^* .

In the univariate problem, the stability of $V^{(0)}$ and $\pi^{(0)}$ are addressed by questions 1 and or through 4. However, the notion of stability is more complicated in the multivariate problem (i.e., multiple parameters). The typical approach to sensitivity analysis for a multivariate problem is to vary one parameter at a time while holding the other parameters constant. This is sometimes referred to as *ordinary sensitivity analysis* [25,26]. However, ordinary sensitivity analysis does not allow for simultaneous variations of different parameters. Bradley *et al.* [27] provided restrictions on the variations in the right-hand side (RHS) terms and objective-function coefficients to guarantee the optimality of the current optimal basis (i.e., optimal decision variables) in a linear program. They term these restrictions as the *100% rule*. Wendell [28] was interested in the range that each parameter was allowed to vary without violating optimality. His approach, which he termed the *tolerance approach*, is different from ordinary sensitivity analysis in that simultaneous variations of different parameters are considered. The tolerance approach has been applied to different problems by various researchers [26,28–31].

It should be clear that the topic of sensitivity analysis is wide and that this section should not be regarded as a comprehensive survey of the approaches that researchers have proposed for sensitivity analysis. Rather, this is a brief discussion of the issues in sensitivity analysis and a presentation of some of the common notions of stability that are applicable to dynamic programs.

DYNAMIC PROGRAMMING

A dynamic program comprises a set of states S , with a set of decisions $A(s)$, available at each $s \in S$. Each $a \in A(s)$ transits the system from a state s to another state s' and results in a reward of r^a . In the deterministic problem (Eq. 1), the state transitions are known with certainty. In the stochastic problem, the state transitions are uncertain (Eq. 2) and the probability of transitioning from state s to state s' under $a \in A(s)$ is denoted by $P^a(s')$. The state transitions are Markovian (i.e., only dependent on the state s' and action a) and stochastic dynamic programs are often referred to as Markov decision processes (MDPs). In this article, we focus on the stochastic problem. However, we note that the discussion and results also apply to deterministic DP since the deterministic problem is merely a special case of the stochastic problem.

Most textbooks divide MDPs into two broad categories: (i) finite horizon and (ii) infinite horizon [6,32,33]. Finite-horizon problems are usually modeled as acyclic graphs where each node corresponds to a particular s at a particular t . The common solution approach for finite-horizon problems is to define the boundary conditions $V_T(s)$ for each state at time T and recursively solve for V in a backward manner:

$$V_{t-1}(s) = \max_{a \in A(s)} \left\{ r^a + \gamma \sum_{s' \in S} P^a(s') V_t(s') \right\} \\ t = 0, 1, \dots, T-1, \forall s \in S, \quad (4)$$

where $V_t(s)$ is the value function of state s at time t . Boundary conditions do not exist for infinite-horizon problems. Infinite-horizon problems are expressed as cyclic graphs and value and/or policy iteration approaches can be used to obtain the optimal solution. These approaches are based on the optimality conditions that are commonly referred to as the *Bellman equations* [33]:

$$V(s) = \max_{a \in A(s)} \left\{ r^a + \gamma \sum_{s' \in S} P^a(s') V(s') \right\} \forall s \in S. \quad (5)$$

It is clear from Equations (1) to (3) that V is continuous in γ . Altman and Schwartz [34] showed that V remains continuous in γ in a constrained MDP. In addition, it also follows from Equations (1) to (3) that V is continuous and monotonic with respect to each individual reward. However, the rewards may not be independent from each other. For example, the cost of producing 10 items may be twice the cost of producing 5 items. In these cases, we are interested in the changes in the optimal solution with respect to the unit cost of production, rather than the cost of producing 10 items specifically. In these problems, the rewards are expressed as

$$r^a = c^a(\rho), \quad (6)$$

where ρ is a vector that represents the parameters that are of interest and $c^a : P \rightarrow \mathbb{R}$, where P is the set containing ρ . White and El-Deib [35] showed that if r^a and $V_T(s)$ are affine in ρ for all $a \in A$ and $s \in S$, the optimal value function of each state, including V , is piecewise affine and concave in ρ .

Modeling the uncertainties in the transition probabilities is complicated by the additional requirement that transition probabilities must add to one. Researchers have modeled the uncertainties in the transition probabilities in a variety of ways [9,10,36–38]. Muller [39] showed that the optimal value function is monotone and continuous when appropriate stochastic orders and probability metrics are used.

Clearly, V is dependent on T . In particular, if all the rewards are nonnegative (nonpositive), V will be monotonically nondecreasing (nonincreasing) in T . However, the former is not a necessary condition and it is possible to prove the monotonicity of V for certain problems, even if the rewards differ in sign. For example, Tan and Hartman [40] showed that the cost of owning and operating equipment is nondecreasing in T if the discount factor and maintenance cost are nonnegative and the salvage value is nonincreasing with age.

Although the value of V is sensitive to changes in the model parameters, their impact on π^* is not as apparent. In fact,

the optimal policy is often robust to minor deviations in the model parameters. White and El-Deib [35] considered an MDP with imprecise rewards and were interested in finding the set of policies that are optimal for some realization of the imprecise parameters. They provided a successive approximation procedure for an acyclic finite-horizon problem and a policy iteration procedure for the infinite-horizon problem. Harmanec [41] computed the set of nondominated policies for a finite-horizon problem with imprecise transition probabilities by generalizing the classical backward recursion approach (Eq. 4).

Researchers have highlighted that the current decision is the only decision that the decision maker has to commit to in many cases and hence, he or she might be solely interested in the optimality of the current decision (i.e., decision at time zero). Hopp [42] was interested in the tolerance on the value functions of the later stages. In particular, he derived lower bounds on the maximum allowable perturbations in the state value of the future stages such that the time zero optimal decision remain unchanged. His numerical results indicate that the tolerance of the value functions (i.e., allowable perturbation) increases geometrically with time. In addition, researchers have also proposed finding a forecast horizon such that the optimal time zero decision is not affected by data beyond that horizon. Researchers who have studied this problem include Bean and Smith [43], Hopp [44], Bean *et al.* [45], and Cheevaprawatdomrong *et al.* [46].

In most cases, it is not necessary to resolve the problem when the model parameters change. Very often, the new π^* and V can be efficiently computed or approximated from the current solution. For example, the optimal solutions to shortest path problems can be easily revised when the arc lengths change [47]. Topaloglu and Powell [48] provided an efficient approach to approximate the change in the optimal value function for a dynamic fleet management model. Their approach was based on the special structure that resulted from their value function approximation. For MDP problems with no special structure, the Bellman equation (5) can be used to verify

the optimality of the current solution. If the optimality conditions are violated, the policy iteration approach can be used to determine the new solution.

LINEAR PROGRAMMING

It has been long recognized that a dynamic program can be formulated and solved as a linear program. The LP method for DP was first proposed by Manne [49] and elaborated upon by Puterman [33] and Derman [50]. It can be shown that a dynamic program can always be formulated by the following linear program [6]:

$$\begin{aligned} & \min \sum_{s \in S} v_s, \\ \text{s.t. } & v_s - \gamma \sum_{s' \in S} P^a(s') v_{s'} \geq r^a, \quad \forall s, a \\ & v_s \in \mathbb{R}, \quad s = 1, 2, \dots, |S|. \end{aligned}$$

The optimal value function V corresponds to $v_{s_0}^*$, where s_0 is the current state (i.e., state at time 0) and π^* is defined by the constraints that are binding at optimality. Manne's observation has an important theoretical implication. It highlights that an optimal solution of a dynamic program will have the same properties as an optimal solution to its associated linear program. This is particularly insightful as sensitivity analysis is well established in LP.

For every linear program, which we will refer to as the *primal Problem*, there is another associated linear program, which is commonly referred to as the *dual problem*. The relationship between the two problems provides insight on the stability of the solution in the primal problem. For each constraint in the primal problem, there is an associated variable in the dual problem. The latter is commonly referred to as the *dual variable*. The complementary slackness theorem, which was first proposed by Goldman and Tucker [51] and extended by Williams [52], highlights the relationship between the variables and constraints of the primal and dual problems at optimality. In particular, if a variable in one problem is positive, the corresponding constraint in

the other problem must be binding. If the constraint is not binding, the corresponding variable in the other problem must be zero. The values of the optimal dual variables, also known as *shadow prices*, correspond to the marginal change in the objective value when the RHS of the associated constraint is perturbed. This result can be applied directly to DP problems where the rewards of individual actions are independent. If a small perturbation to a reward changes some state value function v_s , it follows from the complementary slackness theorem that the associated action must be optimal. If the action is not optimal, its associated reward can be perturbed by a small amount without changing the value of any v_s .

The complementary slackness theorem and economic interpretation of the shadow prices that are presented are only valid when the rewards are independent of each other. When the rewards are dependent, the individual rewards are expressed as functions of independent parameters (Eq. 5) and parametric analysis approaches can be used to analyze the sensitivity of the solution with respect to these independent parameters [53–55]. However, the applicability of LP-based sensitivity analysis approaches to dynamic programs is limited. This is because the number of constraints in the LP formulation is large [6] and hence, dynamic programs are rarely formulated and solved as linear programs in practice.

CONCLUSIONS AND FUTURE RESEARCH

DP is a versatile optimization methodology that can be used to solve a variety of problems. Conventional solution approaches assume that the model parameters are known. However, the parameters are often uncertain in practice and hence the stability of the solution is of interest to the decision maker. The typical approach is to solve the problem for different realizations of parameter values. However, we have highlighted that there are both, theoretical and practical reasons for developing more efficient sensitivity analysis approaches for dynamic programs. Sensitivity analysis is a

well-established topic in LP and can be found in most LP textbooks [55,56]. However, this topic is rarely mentioned, much less discussed, in most DP textbooks [6,32,33,57]. So there is clearly room for development. The following are a few promising areas of future research.

In this article, we have highlighted the relationship between DP and LP and demonstrated how approaches and results from the LP literature can be applied to discrete dynamic programs. However, dynamic programs are rarely solved as linear programs in practice. There is a need to consider sensitivity analysis from a DP perspective and look at approaches that exploit the DP structure of the problem (i.e., Bellman equations).

In the section titled “Dynamic Programming,” we discussed the monotonicity and continuity of V with respect to the model parameters. In particular, we have highlighted that V is not necessarily monotone in T , but it is possible to derive sufficient conditions that guarantee monotonicity. A potential area of research is to explore if more of these sufficient conditions can be derived for specific DP problems (i.e., lot-sizing problem, knapsack problem). Another interesting area of research is to identify additional properties of V and π^* with respect to the model parameters. For example, White and El-Deib [35] highlighted that V is piecewise affine and concave in ρ if r^a and $V_T(s)$ are affine in ρ .

A number of problems that are encountered in practice are large and it is not possible to compute the exact solutions for these dynamic programs. These problems are often solved by approximating the value function and/or aggregating the state space. Topaloglu and Powell [48] were able to exploit the structure of their value function approximation to efficiently revise the solution when the model parameters change. It would be interesting to explore how sensitivity analysis can be performed for different approximate dynamic programs.

Lastly, we note that researchers have typically explored problems where the parameter uncertainties are restricted to

one group of parameters, such as uncertainties solely in the rewards or transition probabilities. However, parameter uncertainty is rarely confined to one particular class of parameters in practice. Hence, researchers should also explore problems where different types of parameters are allowed to vary simultaneously.

SENSITIVITY ANALYSIS IN DECISION MAKING

EMANUELE BORGONOVO
ELEUSI Research Center and
Department of Decision
Sciences, Bocconi University,
Milan, Italy

INTRODUCTION

Sensitivity analysis is one of the main steps of the modern decision-analysis process [1]. In fact, policy and decision-makers, especially in complex situations, benefit from the use of dedicated quantitative support tools for informing their decisions better. Depending on the area of application, they might be dealing with a linear programming model, a decision tree, a probabilistic risk assessment model, or a complex climate change integrated assessment model. Models capture a variety of phenomena and facets and are usually implemented through computer codes, becoming a black box to the manager. However, a manager “*wants to know why. A process starts of finding out what it was about the inputs that made the outputs come out as they did* [2, B469]”. Managerial questions find their answers by shaking the content of a decision-support model through sensitivity analysis. Sensitivity methods are an essential ingredient to draw the maximum information out of a quantitative model [3].

The rigorous application of sensitivity analysis is recommended by several agencies. The U.S. Environmental Protection Agency [4, p. 19], the Florida Commission on Hurricane Loss Projection Methodology [5], and NASA [6] explicitly include the utilization of sensitivity analysis (or importance measures) as part of best practices in their guidelines and procedures.

Several sensitivity analysis methods have been developed over time and numerous are the insights that an analyst can gain from sensitivity analysis. We will discuss them in

the remainder of this article, which is organized as follows. Section titled “Taxonomy and Notation” discusses the sensitivity analysis jargon and notation. Section titled “Local Sensitivity Analysis” presents local sensitivity methods. Section titled “Global Sensitivity Methods” presents global methods, starting with screening methods, continuing to variance-based, distribution-based, and expected value of information-based methods and estimation. Section titled “Sensitivity Analysis Settings” discusses the insights of a sensitivity analysis exercise through the concept of sensitivity analysis setting.

TAXONOMY AND NOTATION

Some taxonomy is necessary to illustrate the basic concepts of sensitivity analysis. First, the mathematical model of interest outputs a set of quantities of interest to the decision-maker. These quantities are called *decision-support criteria* (in the managerial sciences), endogenous variable (in Economics [7]) or, simply, model output (more diffuse in the mathematics and statistics terminology [8]). The quantity of interest is usually denoted by y . y depends on the set of model inputs $\{x_1, x_2, \dots, x_n\}$, which we denote by $\mathbf{x}$. Depending on the sector, we name the elements of $\mathbf{x}$ exogenous variables, factors, parameters, and model inputs. The model is the relationship that binds y to $\mathbf{x}$:

$$g : \mathbf{x} \mapsto y, \quad \Omega_{\mathbf{x}} \rightarrow \Omega_Y, \quad (1)$$

where $\Omega_{\mathbf{x}} \subseteq \mathbb{R}^k$ and $\Omega_Y \subseteq \mathbb{R}$. In Eq. (1), $\Omega_{\mathbf{x}}$ and Ω_Y are the domain of $\mathbf{x}$ and y , respectively. $g(\mathbf{x})$ is not necessarily known analytically and, most often, is the result of complex calculations performed through a computer code.

$u = \{i_1, i_2, \dots, i_k\}$ denotes a subset of indices that refer to any group of k model inputs ($2 \leq k \leq n$) and $\sim u$ the set of remaining model inputs (complementary set). $\mathbf{x}_u = \{x_{i_1}, x_{i_2}, \dots, x_{i_k}\}$ denotes the vector of k model inputs with indices in u .

A symbol of the type I_i (I_u) denotes the sensitivity measure of x_i ($\mathbf{x}_u$).

The computational cost of a sensitivity analysis exercise (C) is conventionally quantified by the number of model runs necessary to estimate the sensitivity measures. For instance, the expression $C = n^2$ is equivalent to saying that computation of the sensitivity measures requires to evaluate the model a number of times equal to the square of the number of model inputs.

LOCAL SENSITIVITY ANALYSIS

The purpose of local sensitivity analysis is to test the response of a decision-support model around some predetermined point of interest, $\mathbf{x}^0 \in \Omega_{\mathbf{x}}$. $\mathbf{x}^0$ is called *base case* or *nominal case*. The simplest form of local sensitivity analysis is represented by tornado diagrams. Their origin can be attributed to Ref. 9. A tornado diagram is a graphical representation of a series of one-factor-at-a-time (OFAT) sensitivities. A tornado diagram is obtained as follows [10]. One assigns a variation range to each factor $[\Delta x_1, \Delta x_2, \dots, \Delta x_n]$. Then, one considers the point $(x_i + \Delta x_i, \mathbf{x}_{-i}^0)$, with x_i moved to the end of its range and the remaining factors fixed at the base case. One then evaluates the differences

$$\Delta^+ y_i = g(x_i + \Delta x_i^+, \mathbf{x}_{-i}^0) - g(\mathbf{x}^0), \quad (2)$$

for all $i = 1, 2, \dots, n$. One also evaluates the differences $\Delta^- y_i = g(x_i - \Delta x_i^+, \mathbf{x}_{-i}^0) - g(\mathbf{x}^0)$.

Usually, the selected variation intervals are symmetric, so that $\Delta x_i^+ = \Delta x_i^- = \Delta x_i$ for all $i = 1, 2, \dots, n$. The results are then displayed as horizontal bars, with the factors ordered by the magnitude of $\Delta^+ y_i$ and $\Delta^- y_i$. Tornado diagrams are widely used in decision-analysis and common commercial software implements them. To illustrate tornado diagrams, we use the following simple example adapted from Ref. 11. Let

$$y = x_1 + \phi x_2 \quad (3)$$

with $0 \leq \phi \leq 1$. For generic variations in $\mathbf{x}$ one obtains

$$\Delta^+ y_i = \Delta x_1 \quad \text{and} \quad \Delta^+ y_2 = \phi \Delta x_2. \quad (4)$$

and

$$\Delta^- y_i = -\Delta x_1 \quad \text{and} \quad \Delta^- y_2 = -\phi \Delta x_2. \quad (5)$$

Selecting $\phi = \frac{1}{2}$, $\Delta x_1 = \frac{1}{2}$, and $\Delta x_2 = \frac{1}{2}$ one obtains the diagram in Fig. 1.

Tornado diagrams can be linked to finite change sensitivity indices, to the method of Morris, and to differential sensitivity [6]. This latter connection is achieved considering $\Delta x_i \rightarrow 0$, and $\lim_{\Delta x_i \rightarrow 0} \frac{\Delta y_i}{\Delta x_i} = \frac{\partial y(\mathbf{x}^0)}{\partial x_i}$. Partial derivatives are the sensitivity measures of interest in two important categories of sensitivity analysis methods: automated differentiation [12] and comparative statics [7]. Moreover, local sensitivity methods play an extremely important role in reliability analysis, field in which they are given the name of

Figure 1. A possible tornado diagram associated with Eq. (3).

importance measures. Importance measures support regulators in risk-informed decision making [13] and in operational decisions concerning graded quality assurance programs, equipment prioritization for maintenance and inspections, and so on.

Reliability importance measures have had an important role also in the general development of sensitivity analysis methods. Historically, the first importance measure is because of Ref. 14. The Birnbaum sensitivity measure starts with a probabilistic interpretation in terms of system failure and represents the probability that component i is critical (we cannot dig into this subject further because of space constraints), and we refer to Ref. 14. Under the assumptions of independent failures and coherent system structure, we can write the Birnbaum importance of input x_i as

$$B_i = \frac{\partial y(\mathbf{x}^0)}{\partial x_i}. \quad (6)$$

Reference 15 shows that B_i can be seen as a particular case of the differential importance measure

$$D_i = \frac{\frac{\partial y(\mathbf{x}^0)}{\partial x_i} dx_i}{\sum_{j=1}^n \frac{\partial y(\mathbf{x}^0)}{\partial x_j} dx_j}. \quad (7)$$

For the differential importance measure the additivity property holds:

$$D_S = \sum_{s=1}^k D_{i_s} \quad (8)$$

$$D_l^T := \frac{\Delta^T G_l}{\Delta G} = \frac{B_l \Delta x_l + \sum_{k=2}^T \sum_{\substack{i_1 < i_2, \dots, i_k \\ l \in i_1 < i_2, \dots, i_k}} J_{i_1, i_2, \dots, i_k}^k(\mathbf{x}^0) \prod_{s=1}^k \Delta x_{i_s}}{\sum_{i=1}^N B_i(\mathbf{x}^0) \cdot \Delta x_i + \sum_{k=2}^T \sum_{i_1 < i_2, \dots, i_k} J_{i_1, i_2, \dots, i_k}^k(\mathbf{x}^0) \prod_{s=1}^k \Delta x_{i_s}}, \quad (11)$$

where $\Delta^T G_l$ is the total change in y provoked by a finite change in the component probabilities ($\Delta \mathbf{x}$). The sum in the extends to order T because the Taylor expansion of a reliability polynomial is exact by the multilinearity of the reliability function polynomial (see Ref. 23 for further details).

and therefore one retrieves the importance of any group of variables as sum of the individual sensitivity measures of the variables in the group. The advantages of this property are discussed in Ref. 15.

A limitation associated with the OFAT nature of the methods presented so far is their inability to display the effects of interactions. Authors have then tried to remedy this shortcoming generalizing the previous definitions including higher order derivatives ([14–22]; for an overview of this process, see Ref. 23). We recall the joint reliability importance measure [16,17], which can be defined as

$$J_{\{i,j\}} = \frac{\partial B_i}{\partial x_j} = \frac{\partial^2 y(\mathbf{x}^0)}{\partial x_j \partial x_i}. \quad (9)$$

Extending the differentiation to higher orders, one obtains the joint reliability importance measure of order k , defined as

$$J_u^k = \frac{\partial^k y(\mathbf{x}^0)}{\partial x_{i_1} \partial x_{i_2} \dots \partial x_{i_k}}. \quad (10)$$

This sensitivity measure provides the strength of the interaction between model inputs $x_{i_1}, x_{i_2}, x_{i_k}$ at $\mathbf{x}^0$.

The total order reliability importance measure [23] brings together in one indicator the Birnbaum and the joint reliability importance measures of all orders. It is defined as

For generic input–output mappings, even when differentiability does not hold, it is shown in Ref. 6 that D_l^T coincide with the total order finite change sensitivity index, which is obtained through a finite-difference decomposition. Finite change sensitivity measures are discussed in the context of inventory management applications in Ref. 24.

Other relevant reliability importance measures are the Fussell-Vesely, the risk achievement worth, and the risk reduction worth importance measures [13], all of which fall in the category of local sensitivity methods.

Local methods inspect the behavior of the model of interest around one reference point. By construction, they are not capable of accounting for uncertainty in $\mathbf{x}^0$. Hence, they ought not to be applied when uncertainty in the model inputs is considered. For this goal, researchers have developed global sensitivity methods.

GLOBAL SENSITIVITY METHODS

In the presence of uncertainty, global methods have become the golden standard of sensitivity analysis [25]. $\mathbf{x} = (x_1, \dots, x_k)$, in the presence of uncertainty becomes a random vector on probability space $(\Omega_{\mathbf{X}}, \mathcal{A}, \mathbb{P}_{\mathbf{X}})$ and is denoted by $\mathbf{X} = (X_1, \dots, X_k)$, a random vector. Correspondingly, $Y = g(\mathbf{X})$ becomes a (function of) random variable. $F_{\mathbf{X}}(\mathbf{x})$ and $F_Y = \mathbb{P}_Y(Y \leq y)$, $f_{\mathbf{X}}(\mathbf{x})$ and $f_Y(\mathbf{x})$ denote the cumulative distributions and probability densities of $\mathbf{X}$ and Y , respectively. Global sensitivity methods can be grouped in the categories of screening [26,27], variance-based [28], expected value of information-based [29], and density-based methods [30].

Screening Methods

Screening methods are designed for identifying the most relevant model inputs with a limited number of model runs. They are usually employed in an initial and exploratory phase, in which the sensitivity of the output on each factor does not need to be determined with extreme precision. The method of Morris consists of performing a series of randomized experiments evaluating the model over proper trajectories (sequences of points that inspects the model input space) and estimating the elementary effects

$$d_i = \frac{\Delta y_i}{\Delta x_i} = g(x_i - \Delta x_i, \mathbf{x}_{-i}^0) - g(\mathbf{x}^0). \quad (12)$$

The effects are then averaged over the trajectory. We refer to Ref. 26 for further details.

The method has, since then, been widely applied and studied. We underline the modifications introduced in Ref. 31.

A further screening method that has been successful in application to simulation codes is sequential bifurcation (SB) [32,33], (see also Ref. 34 for an overview). *SB is a sequential method that changes groups of inputs simultaneously* [[35], p. 1]. We refer to Ref. 35 for a thorough technical account of the method and for its extension into the so-called multi-response SB method.

NonParametric Methods

Historically, in global sensitivity analysis, the family of nonparametric techniques has been the first to be extensively investigated [36,37]. Supposing that the model output is well fitted by a linear regression (i.e., $g(\mathbf{X}) \simeq b_0 + \sum_{s=1}^n b_s X_s$), a natural measure of the sensitivity of Y on X_i is the standardized regression coefficient (SRC) [37]:

$$\text{SRC}_i = \frac{b_i \sigma_i}{\sigma_Y}, \quad (13)$$

where σ_i and σ_Y are the standard deviations of x_i and Y , respectively. If model inputs are independent, then SRC_i coincides with the Pearson regression coefficient

$$\text{PEAR}_i = \frac{\text{Cov}(Y, X_i)}{\sigma_i \sigma_Y}, \quad (14)$$

which is another notable member of the non-parametric methods family. Other representatives of this family are discussed in Refs 36 and [37].

Saltelli and Marivoet [36] demonstrates that the performance of these techniques is synthesized by the model coefficient of determination, R_Y^2 . R_Y^2 is the fraction of the model output variance explained by the regression. When R_Y^2 is low, it becomes “*unrealistic to assess influence of the input variables based on SRC's* [38].” Situations of low R_Y^2 are encountered when models present nonlinearities and interactions. The weakness of these methods can then be overcome in several ways, but two are the main ones. Remaining within the nonparametric method framework, one can define correlations on

ranks, replacing the Pearson correlation with Spearman correlation and using standardized rank regression coefficients (see Ref. 39 for a thorough overview). The second is to resort to variance-based global sensitivity measures. In fact, variance-based methods are capable of accounting for the entire variance of the model output.

Variance-Based Methods

At the basis of variance-based methods is the fundamental result known as *functional analysis of variance (ANOVA) decomposition* of Refs 40,41 (see Ref. 42 for a historical account). Efron and Stein [41] and Sobol' [43] prove that under the assumptions of (i) square integrability of $g(\mathbf{x})$, and (ii) independence of the model inputs [$f_{\mathbf{x}}(\mathbf{x}) = \prod_{i=1}^k f_i(x_i)$], $g(\mathbf{x})$ can be uniquely expanded in $2^n - 1$ terms:

$$g(\mathbf{x}) = g_0 + \sum_{u \neq \emptyset} g_u(\mathbf{x}_u), \quad (15)$$

where $\sum_u$ refers to the sum over all combinations of subsets of indices and $g_u(\mathbf{x}_u)$ is computed from a series of nested integrations:

$$\begin{aligned} g_0 &= \int_{\Omega_{\mathbf{x}}} g(\mathbf{x}) f_{\mathbf{x}}(\mathbf{x}) d\mathbf{x} \\ g_u(\mathbf{x}_u) &= \int_{\Omega_{\sim u}} \left[g(\mathbf{x}_u, \mathbf{x}_{\sim u}) - \sum_{v \subsetneq u} g_v(\mathbf{x}_v) \right] \\ &\quad f_{\sim u}(\mathbf{x}_{\sim u}) d\mathbf{x}_{\sim u}. \end{aligned} \quad (16)$$

As a result, the $g_u(\mathbf{x}_u)$ functions in Eq. (16) are orthogonal [43]. By orthogonality, $\mathbb{V}[Y] = \mathbb{E}[(g(\mathbf{x}) - g_0)^2]$ can be expressed as

$$\mathbb{V}[Y] = \sum_u V_u(\mathbf{x}_u), \quad (17)$$

with

$$V_u = \int_{\Omega_u} [g_u(\mathbf{x}_u)]^2 f_u(\mathbf{x}_u) d\mathbf{x}_u. \quad (18)$$

By Eqs (17) and (18), the functional decomposition of $g(\cdot)$ is in one-to-one correspondence with the decomposition of its variance.

From Eqs (17) and (18), Ref. 28 defines the so-called variance-based sensitivity index of order k as

$$S_u^k = \frac{V_u}{\mathbb{V}[Y]}. \quad (19)$$

Clearly, $\sum_{r=1}^k \sum_{u:|u|=r} S_u^k = 1$. Of particular relevance are the first order indices

$$S_i^1 = \frac{V_{\{i\}}}{\mathbb{V}[Y]} \quad (20)$$

and the total order indices

$$S_i^T = \frac{\sum_{u:u \ni i} V_u}{\mathbb{V}[Y]}, \quad (21)$$

where $\sum_{u:u \ni i}$ denotes a sum extended to all u that include index i . S_i^T is the portion of $\mathbb{V}[Y]$ associated with X_i and all its interactions with the remaining model inputs. Under the independence assumption, it can be proven that S_i^T is the fraction of $\mathbb{V}[Y]$ remaining after all factors are fixed, leaving the sole X_i free to vary.

From a historical viewpoint, the sensitivity measures have appeared in unrelated journal articles in different fields in the early 1990s. Iman and Hora [44] define variance-based sensitivity measures as $IH_i = \mathbb{V}[\mathbb{E}[Y|X_i]]$ in the context of reliability analysis. It can be proven that, under the independence assumption, I_i is the numerator of S_i^1 . In the same years [45] defines Sobol' sensitivity indices in Eqs (19), (20), and (21) under the independence assumption. Autonomously, Wagner [46] arrives at the definition of a non-normalized versions of both the first (S_i^1) and total order (S_i^T) variance-based measures. Wagner's definition does not rely on the independence assumption.

Variance-based measures might be subject to a misleading interpretation, if one considers them as *the expected reduction in uncertainty due to observing x_i* [47, p. 753]. In fact, what reflects a decision-maker state of knowledge about an uncertain quantity is its distribution [48]. A distribution is completely summarized by variance, under the normality assumption [48]. Similarly, risk is completely characterized by variance only

under a quadratic utility assumption [49]. In Ref. 50, a counterexample shows that stretching the interpretation of variance as representative of uncertainty leads to misleading conclusions in sensitivity analysis.

The study of variance-based sensitivity measures in the presence of dependencies among the model inputs is attracting increasing attention. The interest stems from results in Refs 47 and 51. Bedford [51] shows that the uniqueness of the decomposition in eq. (15) is lost in the presence of dependencies. Oakley and O'Hagan [47] show that terms not related to the functional structure of $g(\mathbf{x})$ emerge in Eq. (15), when correlations are present. Several authors have recently proposed alternative approaches and research is ongoing [52–55].

Density-Based Methods

A class of global sensitivity measures that considers the entire distribution without reference to a particular moment and whose sensitivity measures are well posed in the presence of correlations is the class of density-based methods [30,50,56–58]. The key intuition is to base the sensitivity measures on a comparison of the conditional model output density $f_{Y|X_i}(y)$ and the unconditional model output density $f_Y(y)$. Because of its properties, a widely studied representative of this class is the δ -sensitivity measure introduced in Ref. 30 (also known as *Borgonovo's- δ*) and defined as

$$\delta_i = \frac{1}{2} \mathbb{E} \left[\int_{\Omega_Y} |f_Y(y) - f_{Y|X_i}(y)| dy \right] dx_i, \quad (22)$$

δ_i is a method of recent introduction and attracting increasing attention both concerning its properties and estimation [59,60]. δ_i shares several convenient properties such as normalization ($0 \leq \delta_i \leq 1$), and monotonic transformation invariance. It can be shown [61] that

$$\delta_i = \frac{1}{2} \int_{\Omega_{X_i} \times \Omega_Y} |f_{Y|X_i}(y) - f_Y(y)f_{X_i}(x_i)| dy dx_i. \quad (23)$$

In fact, if Y (the model output) is independent of X_i , then the joint distribution $f_{YX_i}(y)$ is equal to the product of the marginal distributions $f_Y(y)f_{X_i}(x_i)$ and $\delta_i = 0$. The converse also holds. Thus, δ_i is a measure of statistical dependence, rather than of functional dependence.

Transformation Invariant Global Sensitivity Statistics

Monotonic transformation invariance is a property particularly convenient from both a theoretical and a numerical viewpoint. From a decision-analysis viewpoint, often the quantity of interest is not only Y (the model output), but a utility on Y , $u(Y)$. The assignment of the exact functional form to $u(Y)$ might be a cumbersome task [11]. However, if the sensitivity measure is monotonic transformation invariant, its results are unaffected by imprecision in the assessment of $u(Y)$ [11].

Perhaps the most notable advantage of monotonic transformation invariance is related to computation. When the model output is sparse (it ranges several orders of magnitudes) it becomes difficult to obtain convergence of the numerical algorithms that estimate global sensitivity measures. In these cases, analysts resort to transformations of Y for improving numerical accuracy in the estimation. The most widely used are the lognormal and the rank transformations. *The problem associated with estimating the variance of long-tailed distributions is directly attributable to the scale of the numbers involved. The scaling problem most often can be overcome by performing uncertainty importance calculations based on a logarithmic scale* [[44], p. 402]. If the sensitivity measure is transformation invariant, then analysts can exploit the advantage of the transformation avoiding the problem of transferring results of the analysis back to the original data.

A set of transformation invariant sensitivity measures are recently discussed in Ref. 11. Their definition is proposed as

$$\beta_d^Y = \mathbb{E}_i [d(F_Y, F_{Y|X_i})], \quad (24)$$

where $d(F_Y, F_{Y|X_i})$ is any distance between distribution functions which is monotonic transformation invariant. The Kuiper and Kolmogorov–Smirnov metrics are discussed in Ref. 11. Their properties are studied for decision-problem involving investment opportunities.

Value of Information-Based Sensitivity Measures

All the sensitivity measures we have discussed so far are value-based sensitivity measures. None of them captures decision-sensitivity. That is, using a nonparametric, a variance-based, and a distribution-based global sensitivity measure, an analyst is looking at uncertainty in Y and how it is apportioned by its sources. However, in several decision-analysis problems, the decision maker is selecting among competing alternatives under uncertainty. The model output is, in these cases, of the form $Y = \max_{1, 2, \dots, n}(\mathbb{E}[Y_1(\mathbf{X})], \mathbb{E}[Y_2(\mathbf{X})], \dots, \mathbb{E}[Y_n(\mathbf{X})]) = \max_j[\mathbb{E}[Y_j(\mathbf{X})]]$. In that case, getting to know X_i not only changes the distribution of Y , but might change the preferred alternative. The sensitivity measure that captures both decision-sensitivity and value sensitivity is the partial value of expected information [29,62,63].

$$\epsilon_i = \mathbb{E}_{X_i} \left[\max_j \{ \mathbb{E}[Y_j|X_i] \} \right] - \max_j \{ \mathbb{E}[Y_j(\mathbf{X})] \}. \quad (25)$$

The expected value of perfect information can be interpreted as “the difference between the expected profit that we shall obtain as a result of the clairvoyance and the expected profit that we would obtain without the clairvoyance” [64] on X_i . ϵ_i is discussed in decision-making applications with particular reference to the medical sector in Refs 29 and 62. It is also proposed as an importance measure for decision making in reliability in Ref. 65.

Estimation

The estimation of global sensitivity measures has been the subject of investigation in numerous works [28,66–68] and ongoing

research is vast. The reason is that the analytical estimation of global sensitivity measures is possible in a few cases [69]. However, in most applications, the input–output mapping $g(\mathbf{x})$ is not known analytically, and the sensitivity measures need to be computed numerically. The numerical estimation consists of the generation of an appropriate sample followed by the evaluation of the model at the corresponding points. The size of the sample is denoted by N . This step is often called (although with some vagueness in the terminology) *Monte Carlo simulation* or *uncertainty analysis*. Among the sample generation methods, we recall Latin Hypercube [70,71], Sobol’ quasi random LpTau [72], and Halton sequences [73].

The design of the Morris method is associated with a cost $C = 2 \times r \times n$, where r is the number of replicates for each factor.

No particular design is required in the estimation of nonparametric techniques, which can be obtained directly from the sample generated by a Monte Carlo simulation. Their cost is equal to $C = N$ model evaluations.

Variance-based, density-based, distribution-based, and value of information-based sensitivity measures are associated with a cost of $C = n^2N$, if a brute force estimation strategy is envisioned. For variance-based sensitivity measures, however, notable computational burden reduction results have been obtained in Refs 74 and 75, with the computation cost lowered to $C = (k + 2)N$. However, most recently, the works [61,76], and [77] show that all global sensitivity measures can be estimated at the same cost of nonparametric methods, further lowering the computational cost to $C = N$ model runs. Thus, state-of-the art allows the estimation of all first order global sensitivity measures directly following a Monte Carlo simulation, without the need of a specific design.

For computationally intensive models, the estimation might be carried in two steps, with the first step being the reduction of the model through a metamodel. Alternative types of metamodeling methods are discussed in Refs 68,78–84.

SENSITIVITY ANALYSIS SETTINGS

An important aspect of a sensitivity analysis is to clearly establish its goals. Often the goal of a sensitivity analysis is specific and tailored to answer a very particular question. This creates issues especially when the unclear statement of the question leads analysts to utilize methods not consistent with the goal or with their degree of belief. The clearest example is the utilization of local methods in the presence of uncertainty. For this reason, the literature has elaborated ways for making the use of sensitivity analysis methods systematic introducing the concept of sensitivity analysis setting [8,24]. A setting is a formulation of the sensitivity analysis problem that allows the analyst to select the most appropriate method for obtaining the desired answer. A setting must be stated before the sensitivity analysis is executed. On the basis of an investigation of different types of problems that have been encountered in the literature, we can identify the following main settings. *Robustness analysis* (For a thorough overview of robustness analysis, we refer to Refs 85–87.) In decision analysis, a relevant goal of sensitivity analysis is to find the region of Ω_X such that the optimal policy remains unchanged. In connection with influence-diagrams, methods for robustness are discussed in Refs 88–90. In problems supported by Bayesian networks, robustness analysis is discussed in Refs 91–93. The tolerance sensitivity approach of Wendell [94,95] is a robustness approach developed for linear programming problems. In a tolerance sensitivity analysis the goal is to find the variation of the parameters of a linear programming problem that insures the stability of the optimal basis.

A second setting is *factor prioritization* [8]. In a factor prioritization, the goal of the analysis is to rank factors based on their influence on the model output. The complementary setting, that is, identifying the factors that matter the least on the output variation is called *factor fixing* [96]. According to Ref. 97, screening methods find their collocation within this setting. Of interest for decision-makers is also the appreciation of the sign of

change of the model output given a change in the model inputs. This setting is at the basis of the comparative statics method in Economics [7], and is formalized as the *direction of change* setting in Ref. 24. Of further relevance to the decision-maker is to understand the model structure, that is, whether the action of a model input is individual or because of its interactions with other factors. This can be formalized in the *model structure* setting [24].

SENSITIVITY ANALYSIS IN LINEAR PROGRAMMING

CARLO FILIPPI
Department of Quantitative
Methods, University of
Brescia, Brescia, Italy

Sensitivity analysis in linear programming studies the stability of optimal solutions and the optimal objective value with respect to perturbations in the input data. This analysis is often relevant in practical applications. Usually, data are estimates of unknown parameters, such as prices of raw materials, customer demands, and travel times. In this case, the decision maker may want to know if better estimates are required before making decisions. For instance, if a parameter is not exactly known, but sensitivity analysis implies that the solution associated with the available parameter estimate remains optimal for a wide range of values around it, then a better, more expensive estimate may not be required. Conversely, if a sensitivity analysis shows that the optimal solution changes with a small perturbation of the parameter value, then a better estimate might be crucial before making any decision. It may also happen that some parameters, such as the availability of certain resources, are not exactly known simply because the decision maker can vary their values within a certain range without changing the structure of the problem. In this case, sensitivity analysis may help the decision maker to choose the most appropriate values of the parameters. Evaluating stability of the model output in front of small perturbations of the input data may be useful also for model validation.

Input data in a linear program are the constraint matrix, the right-hand side vector, and the objective vector. Once a linear program has been solved, a decision maker may ask questions such as the following:

- What happens to the obtained solution when the right-hand side/objective vector is perturbed?
- What is the rate of change in the optimal value when the right-hand side/objective vector is perturbed?
- In what region/interval may such a vector be varied while maintaining the same rate of change?

We discuss different approaches for answering questions like those. We focus on the effects of perturbations in the right-hand side and objective vectors, since such perturbations represent the most significant cases in practice. Perturbations on the constraint coefficient matrix are hard to handle analytically, and often a simple what-if analysis on different values of the sensible coefficients seems more appropriate than a sensitivity analysis.

Sensitivity analysis is often associated with parametric programming (see **Parametric LP Analysis**). In fact, these topics share many common features, but the focus is different: sensitivity analysis deals with the effects of local perturbations of parameters, whereas parametric programming is concerned with a systematic description of the optimal solution and the optimal value as explicit functions of the parameters.

PRELIMINARIES AND NOTATION

Consider the following primal and dual optimization problems in standard form (see **The Simplex Method and Its Complexity**):

$$(P) \quad \max\{c^T x : Ax = b, x \geq 0\},$$

$$(D) \quad \min\{y^T b : y^T A \geq c^T\},$$

where A is an $m \times n$ real matrix with full row rank, and c, b, x , and y are real vectors of appropriate size. Let $E = \{1, 2, \dots, n\}$ and $M = \{1, 2, \dots, m\}$; let the columns and the rows of A be indexed by E and M respectively, according to the natural ordering. For any $J \subseteq E$, let x_J be the subvector of x indexed by J and let A_J be the submatrix of A consisting of columns indexed by J . In particular, x_j is

the j th entry of vector x . A *basis* is a subset B of m elements of E such that A_B is nonsingular. A *cobasis* is the complement of a basis: $N = E \setminus B$.

The *primal basic solution* associated with basis B is the n -vector $p = (p_B, p_N) = (A_B^{-1}b, 0)$; the *dual basic solution* associated with basis B is the m -vector $d = (c_B^T A_B^{-1})^T$. The basis B is *primal feasible* if the associated primal basic solution is feasible, that is if $p_B \geq 0$; *dual feasible* if the associated dual basic solution is feasible, that is if $d^T A_N \geq c_N^T$. The basis B is *primal degenerate* if vector p_B has some zero entry; *dual degenerate* if vector $c_N^T - d^T A_N$ has some zero entry (see **Degeneracy and Variable Entering/Exiting Rules**). The basis B is *optimal* if it is both primal and dual feasible. If B is optimal, then the optimal value of the objective function is

$$z^* = c_B^T A_B^{-1} b = c_B^T p_B = d^T b.$$

Consider the following illustrative example:

$$\begin{aligned} \max \quad & 4x_1 + 5x_2 \\ \text{subject to} \quad & x_1 + x_2 \leq 10 \\ & x_1 + 3x_2 \leq 18 \\ & x_1, x_2 \geq 0. \end{aligned}$$

The feasible region is shown in Fig. 1. The unique optimal solution is the corner point $x = (6, 4)^T$. The equivalent standard form of the above model is

$$\begin{aligned} \max \quad & 4x_1 + 5x_2 \\ \text{subject to} \quad & x_1 + x_2 + x_3 = 10 \\ & x_1 + 3x_2 + x_4 = 18 \\ & x_1, x_2, x_3, x_4 \geq 0, \end{aligned}$$

where $c = (4, 5, 0, 0)^T$, $b = (10, 18)^T$, and

$$A = \begin{bmatrix} 1 & 1 & 1 & 0 \\ 1 & 3 & 0 & 1 \end{bmatrix}.$$

The unique optimal solution $(6, 4, 0, 0)^T$ is the primal basic solution associated with basis $B = \{1, 2\}$ and cobasis $N = \{3, 4\}$. We have

$$A_B^{-1} = \begin{bmatrix} 3/2 & -1/2 \\ -1/2 & 1/2 \end{bmatrix},$$

Figure 1. Feasible region of the illustrative example (shaded polygon) and slope of the objective function (dashed line).

hence $p_B = (6, 4)^T$, $p_N = (0, 0)^T$, $d = (7/2, 1/2)^T$. It is easy to check that B is optimal and that B is both primal and dual nondegenerate. The optimal value is $z^* = 44$.

NONDEGENERATE CASE

The Perturbed Problem

Consider a pair of problems (P) and (D) for fixed input A, b , and c . Let $B \subseteq E$ be an optimal basis, both primal and dual nondegenerate. Let $v \in \mathbb{R}^m$ and $w \in \mathbb{R}^n$ be perturbation vectors for the right-hand side vector b and the objective vector c respectively, and consider the perturbed problem:

$$(P(v, w)) \quad \max\{(c + w)^T x : Ax = b + v, x \geq 0\}.$$

The standard approach to sensitivity analysis in linear programming is to characterize the perturbation vectors v and w that preserve the optimality of B . The primal basic solution associated with B in $(P(v, w))$ is

$$p(v) = (p_B(v), p_N(v)) = (p_B + A_B^{-1}v, 0),$$

the dual basic solution is

$$d(w) = d + (w_B^T A_B^{-1})^T.$$

Notice that perturbations on the right-hand side vector affect only the primal basic solution, and thus may affect the primal feasibility of the basis, but not its dual feasibility. Conversely, perturbations on the objective vector affect only the dual basic solution, and thus may affect the dual feasibility of the basis, but not its primal feasibility. Moreover, the dual basic solution is not affected by perturbations on the objective coefficients corresponding to the cobasis N .

Consider the following polyhedral cones [1]:

$$\begin{aligned} C_P &= \{v \in \mathbb{R}^m : -A_B^{-1}v \leq p_B\}, \\ C_D &= \{w \in \mathbb{R}^n : w_N^T - w_B^T A_B^{-1} A_N \\ &\leq -(c_N^T - d^T A_N)\}. \end{aligned}$$

We call C_P and C_D respectively the *primal* and *dual basic cone* associated with B . Primal nondegeneracy implies that $v = 0$ lies in the interior of C_P ; dual nondegeneracy implies that $w = 0$ lies in the interior of C_D . One can check that $p(v) \geq 0$, and thus B is primal feasible for $(P(v, w))$, if and only if $v \in C_P$. Furthermore, $d(w)^T A \geq c^T$, and thus B is dual feasible for $(P(v, w))$, if and only if $w \in C_D$.

If $v \in C_P$ and $w \in C_D$, then B is optimal and the optimal objective value is expressed as follows:

$$\begin{aligned} z(v, w) &= (c_B + w_B)^T A_B^{-1} (b + v) \\ &= z^* + d^T v + w_B^T p_B + w_B^T A_B^{-1} v. \end{aligned}$$

Notice that $z(v, w)$ is a quadratic function of v and w , in general neither convex nor concave. However, if we fix a value $v' \in P$, then $z(v', w)$ is an affine function of w , and if we fix a value $w' \in D$, then $z(v, w')$ is an affine function of v . In particular,

$$z(v, 0) = z^* + d^T v,$$

so that the dual vector d is the gradient of $z(v, 0)$ with respect to v in the interior of C_P . Similarly,

$$z(0, w) = z^* + w_B^T p_B,$$

so that the primal vector p is the gradient of $z(0, w)$ with respect to w in the interior of C_D . In fact, d is often called the vector of *shadow prices* for the entries of b , whereas p_B is often called the vector of *shadow costs* for the variables in x_B (the shadow costs of the variables in x_B are always zero).

In our example, the primal and dual basic cones are respectively

$$\begin{aligned} C_P &= \{v \in \mathbb{R}^2 : -(3/2)v_1 + (1/2)v_2 \leq 6; \\ &\quad (1/2)v_1 - (1/2)v_2 \leq 4\}, \\ C_D &= \{w \in \mathbb{R}^4 : w_3 - (3/2)w_1 + (1/2)w_2 \leq 7/2; \\ &\quad w_4 + (1/2)w_1 - (1/2)w_2 \leq 1/2\}. \end{aligned}$$

The first cone is depicted in Fig. 2. Notice that every choice of $v \in C_P$ corresponds to a translation of the constraints of the feasible region such that the corner point is still a primal feasible solution; every choice of $w \in C_D$ corresponds to a rotation of the objective vector such that the corner point is still a dual feasible solution.

Ordinary Sensitivity Analysis

From a theoretical point of view (and considering only the nondegenerate case), the cones C_P and C_D , and the expressions $p(v)$, $d(w)$, and $z(v, w)$, fully characterize the stability

Figure 2. Optimal primal basic cone in the illustrative example.

of B . From a practical point of view, the description of C_P and C_D may be difficult to interpret for a decision maker. Even in our toy example, C_D is a four-dimensional object, impossible to visualize exactly. This drawback may be overcome by restricting attention to variations of a single entry of either the right-hand side or the objective vector at a time. In other words, for every coefficient, we look for the *critical interval* where such a coefficient may vary without affecting the optimality of the current basis, while all other coefficients are fixed to their original values. Such an approach is known as *ordinary* sensitivity analysis and it is usually implemented in commercial packages for linear optimization.

More specifically, for all $i \in M$, we let $v = \beta e^{(i)}$, where β is a scalar and $e^{(i)}$ is the m -vector with entry 1 in i th position, 0 elsewhere. In this way, we consider just the intersection of the primal basic cone with the i th coordinate axis, and we obtain an interval I_i , possibly unbounded, containing 0, and such that basis B remains primal feasible and thus optimal, if and only if $\beta \in I_i$. The computation of I_i proceeds as follows. Let α_{ki} denote the entry of A_B^{-1} on the row indexed by $k \in B$ and the column indexed by $i \in M$. By imposing $v = \beta e^{(i)}$, the conditions $-A_B^{-1}v \leq p_B$ defining C_P boil down to

$$-\beta \alpha_{ki} \leq p_k \quad \text{for all } k \in B,$$

that is,

$$\begin{aligned} \beta &\geq -p_k / \alpha_{ki} & \text{for all } k \in B \text{ with } \alpha_{ki} > 0, \\ \beta &\leq -p_k / \alpha_{ki} & \text{for all } k \in B \text{ with } \alpha_{ki} < 0. \end{aligned}$$

The last two conditions define the extrema of I_i . If $\alpha_{ki} \leq 0$ for all $k \in B$, then I_i is unbounded from below; if $\alpha_{ki} \geq 0$ for all $k \in B$, then I_i is unbounded from above. Note that all data needed for computation are directly available in the simplex tableau corresponding to B (see **The Simplex Method and Its Complexity**).

Analogously, for all $j \in E$, we let $w = \gamma e^{(j)}$, where γ is a scalar and $e^{(j)}$ is the n -vector with entry 1 in j th position, 0 elsewhere. In this way, we obtain an interval J_j , possibly unbounded, containing 0, and such that basis

B remains dual feasible and thus optimal if and only if $\gamma \in J_j$. The computation of J_j proceeds as follows. If $j \in N$, then the conditions $w_N^T - w_B^T A_B^{-1} A_N \leq -(c_N^T - d^T A_N)$ defining C_D boil down to the unique condition

$$\gamma \leq -(c_j - d^T A_j),$$

so that J_j is unbounded from below. Notice that $r_j = c_j - d^T A_j$ is often called the *reduced cost coefficient* of the primal variable x_j with respect to basis B . If $j \in B$, then the conditions defining C_D boil down to

$$-\gamma \sum_{i \in M} \alpha_{ji} a_{ik} \leq -r_k \quad \text{for all } k \in N,$$

where a_{jk} denotes the entry of A_N on the row indexed by $j \in B$ and the column indexed by $k \in N$. Thus we have

$$\begin{aligned} \gamma &\geq r_k / \left(\sum_{i \in M} \alpha_{ji} a_{jk} \right) & \text{for all } k \in N \text{ with} \\ &\sum_{i \in M} \alpha_{ji} a_{ik} > 0, \\ \gamma &\leq r_k / \left(\sum_{i \in M} \alpha_{ji} a_{jk} \right) & \text{for all } k \in N \text{ with} \\ &\sum_{i \in M} \alpha_{ji} a_{ik} < 0. \end{aligned}$$

The last two conditions define the extrema of J_j . If $\sum_{i \in M} \alpha_{ji} a_{jk} \leq 0$ for all $k \in N$, then J_j is unbounded from above; if $\sum_{i \in M} \alpha_{ji} a_{jk} \geq 0$ for all $k \in N$ then J_j is unbounded from below. Again, all data needed for computation are directly available in the simplex tableau corresponding to B . In particular, $\sum_{i \in M} \alpha_{ji} a_{jk}$ is simply the entry of the tableau on the row and column indexed by j and k respectively.

In our small example, if we let $v = (\beta, 0)^T$, then we get

$$C_P \cap \{(\beta, 0) : \beta \in \mathbb{R}\} = \{(\beta, 0) : -4 \leq \beta \leq 8\},$$

and thus $I_1 = [-4, 8]$. If we let $v = (0, \beta)^T$, then we get

$$C_P \cap \{(0, \beta) : \beta \in \mathbb{R}\} = \{(0, \beta) : -8 \leq \beta \leq 12\},$$

and thus $I_2 = [-8, 12]$. The cuts originating these intervals are evidenced in Fig. 3.

Figure 3. Ordinary sensitivity analysis: cuts of the primal basic cone originating the right-hand side intervals (bold segments).

Similarly, ordinary sensitivity analysis with respect to the objective coefficients lead to the following intervals:

$$\begin{aligned} J_1 &= [-7/3, 1], J_2 = [-1, 7], \\ J_3 &= (-\infty, 7/2], J_4 = (-\infty, 1/2]. \end{aligned}$$

As already noticed, for a nonbasic index j it always happens that the interval returned by ordinary sensitivity analysis has the form $(-\infty, -r_j]$, where r_j is the reduced cost coefficient of x_j with respect to the current basis. The objective coefficients c_j with $j \in N$ may be perturbed simultaneously and independently inside their corresponding intervals, maintaining the optimality of B . However, in general the critical intervals obtained by ordinary sensitivity analysis are not valid when different coefficients vary simultaneously, and this is a severe restriction to their applicability. The next two approaches to sensitivity analysis try to surmount this restriction.

The 100% Rule

The 100% rule exploits two facts: (i) the intervals obtained from ordinary sensitivity analysis are subsets of the basic cones, and (ii) the basic cones are convex sets [1]. Hence, any convex combination of points contained

in critical intervals is contained in the corresponding basic cone and thus, the corresponding perturbation preserves the optimality of the current basis while allowing simultaneous perturbations of the coefficients.

Let us focus on right-hand side perturbations, and assume for simplicity of exposition, that the critical interval $I_i = [s_i, f_i]$ is bounded for all $i \in M$. Then, the convex hull of the critical intervals is expressed by the inequalities

$$\sum_{i \in M} (v_i / \omega_i) \leq 1,$$

where $\omega_i \in \{s_i, f_i\}$, for all $i \in M$ [2].

Coming back to our example, the ordinary sensitivity analysis of the right-hand side coefficients has led to the intervals $I_1 = [s_1, f_1] = [-4, 8]$ and $I_2 = [s_2, f_2] = [-8, 12]$. The convex hull of these two intervals, that is the 100% region, is then described by the following inequalities:

$$\begin{aligned} v_1/(-4) + v_2/(-8) &\leq 1, \\ v_1/(-4) + v_2/12 &\leq 1, \\ v_1/8 + v_2/(-8) &\leq 1, \\ v_1/8 + v_2/12 &\leq 1. \end{aligned}$$

(Fig. 4). The description of the 100% region associated with the objective coefficients can be derived similarly.

In general, we have a set difficult to interpret: the description of the 100% region requires 2^m inequalities in case of right-hand side perturbations, 2^n in case of objective perturbations. However, the idea is to generate only the inequalities that are strictly required. For example, if we are interested only in perturbations that increase the right-hand side coefficients, we need to check only one inequality, namely $\sum_{i \in M} (v_i / f_i) \leq 1$.

The Tolerance Approach

The *tolerance approach* focuses on simultaneous and independent variations of the right-hand side and objective coefficients. Independent means that for every b or c coefficient an interval of allowable perturbation is specified, and every entry of b and c is free to vary inside its interval. In its

Figure 4. The 100% rule: region of allowed right-hand side perturbations (dark polygon).

most simple form, the tolerance approach returns a unique numerical value (*tolerance*) representing the maximum additive perturbation which can be applied on each b or c coefficient without affecting the optimality of the given basis. In this sense, the tolerance approach tries to resolve the trade-off between allowing multidimensional perturbations and giving clear results.

Consider right-hand side perturbations. We want to specify a unique interval $[-\rho, +\rho]$, such that if $v_i \in [-\rho, +\rho]$ for all $i \in M$, then basis B remains primal feasible (and thus optimal), and we want to get the largest possible interval. Geometrically, we look for the largest hypercube centered in the origin and contained in the primal basic cone C_P . Let an *allowable right-hand side tolerance* be a nonnegative value ρ such that

$$\{v \in \mathbb{R}^m : -\rho \leq v_i \leq +\rho \text{ for all } i \in M\} \subseteq C_P.$$

The *maximum right-hand side tolerance* ρ^* is the largest allowable right-hand side tolerance. Let again α_{ki} denote the entry of A_B^{-1} on the row indexed by $k \in B$ and the column indexed by $i \in M$. For all $k \in B$, let

$$\rho_k = p_k / \sum_{i \in M} |\alpha_{ki}| = \sum_{i \in M} \alpha_{ki} b_i / \sum_{i \in M} |\alpha_{ki}|.$$

It can be proved that [3]

$$\rho^* = \min\{\rho_k : k \in B\}.$$

Returning to our example, we have

$$\begin{aligned} \rho^* &= \min\{6/(3/2+1/2); 4/(1/2+1/2)\} \\ &= \min\{3; 4\} = 3. \end{aligned}$$

Thus, the two right-hand side perturbations v_1 and v_2 may vary simultaneously and independently in the same interval $[-3, +3]$ without affecting the primal feasibility, and hence the optimality, of the current basis. The corresponding tolerance region is depicted in Fig. 5 (dark square). A value of ρ larger than 3 would result in a tolerance region not contained in the primal basic cone C_P . However, if we relax the requirement that each coefficient has the same interval and that each interval is centered in the origin, we may obtain a larger region.

More precisely, we can define *allowable individual right-hand side tolerances* as non-negative scalars ρ^-_i and ρ^+_i such that if $-\rho^-_i \leq v_i \leq +\rho^+_i$ for all $i \in M$, then the current basis remains optimal. Let the values $\rho_k (k \in B)$ be computed as before. It can be

Figure 5. Tolerance approach: region of allowed right-hand side perturbations with unique tolerance (dark square) and with individual tolerances (light grey rectangle containing the dark square).

proved [4] that the following, easily computable values are allowable individual right-hand side tolerances:

$$\begin{aligned}\rho^{*-}_i &= \min\{\rho_k : k \in B; \alpha_{ik} < 0\}, \\ \rho^{*+}_i &= \min\{\rho_k : k \in B; \alpha_{ik} > 0\} \\ &\text{for all } i \in M.\end{aligned}$$

Since all ρ^{*-}_i and ρ^{*+}_i are minima over a subset of the ρ_k , whereas ρ^* is the minimum over all the ρ_k , we have $\rho^{*-}_i \geq \rho^*$ and $\rho^{*+}_i \geq \rho^*$ for all $i \in M$, so that

$$\begin{aligned}\{v \in \mathbb{R}^m : -\rho^{*-}_i \leq v_i \leq +\rho^{*+}_i \text{ for all } i \in M\} \supseteq \\ \{v \in \mathbb{R}^m : -\rho^* \leq v_i \leq +\rho^* \text{ for all } i \in M\}.\end{aligned}$$

In our example, it turns out that $\rho^{*-}_1 = \rho^{*+}_2 = \rho_1$ and $\rho^{*+}_1 = \rho^{*-}_2 = \rho_2$. The corresponding tolerance region is depicted in Fig. 5 (light gray rectangle containing the dark square).

Analogous tolerances can be computed for objective vector perturbations [3,4].

DEGENERATE CASE

When primal and/or dual degeneracy occurs in the optimal basis, then sensitivity analysis becomes harder to perform and to interpret correctly. We first analyze the difficulties related to degeneracy and then sketch some possible solutions.

Primal Degeneracy

Primal degeneracy usually implies that the same optimal solution can be associated with different optimal bases and to different dual solutions (see **Degeneracy and Variable Entering/Exiting Rules**). Geometrically, this means that the null right-hand side perturbation vector, $v = 0$, lies on the boundary of different basic cones, and that in each basic cone, the optimal value can be a different function of the perturbations. As a consequence, the optimal value function $z(v, 0)$ is not differentiable with respect to v . To clarify this point, let us modify the

right-hand side vector of the toy example considered so far:

$$\begin{aligned}\max \quad & 4x_1 + 5x_2 \\ \text{subject to} \quad & x_1 + x_2 + x_3 = 10 \\ & x_1 + 3x_2 + x_4 = 30 \\ & x_1, x_2, x_3, x_4 \geq 0.\end{aligned}$$

With the new right-hand side vector, the unique optimal solution becomes $p^* = (0, 10, 0, 0)^T$ with optimal value $z^* = 50$. The simplex method could correctly certify that p^* is associated with basis $B = \{1, 2\}$. As a consequence, the obtained dual solution is $d = (7/2, 1/2)^T$ and the obtained primal basic cone is

$$\begin{aligned}C_P = \{v \in \mathbb{R}^2 : -(3/2)v_1 + (1/2)v_2 \leq 0; \\ (1/2)v_1 - (1/2)v_2 \leq 10\}.\end{aligned}$$

As explained above, if $v \in C_P$ then B remains optimal and the optimal value is expressed as

$$z(v, 0) = z^* + d^T v = 50 + (7/2)v_1 + (1/2)v_2.$$

In particular, ordinary sensitivity analysis returns two intervals, $I_1 = [0, 20]$ and $I_2 = [-20, 0]$, that should be interpreted as follows: if $v_2 = 0$, then the slope of the objective value is 7/2 as long as $v_1 \in I_1$; if $v_1 = 0$, then the slope of the objective value is 1/2 as long as $v_2 \in I_2$. This is correct, but it is only a partial truth. Indeed, due to primal degeneracy, p^* is also associated with basis $B' = \{4, 2\}$. If we consider B' , we have the dual solution $d' = (5, 0)^T$ and the primal basic cone

$$C'_P = \{v \in \mathbb{R}^2 : 3v_1 - v_2 \leq 0; -v_1 \leq 10\}.$$

If $v \in C'_P$, then B' remains optimal and the optimal value is expressed as

$$z(v, 0) = z^* + (d')^T v = 50 + 5v_1.$$

In particular, ordinary sensitivity analysis returns other two intervals, $I'_1 = [-10, 0]$ and $I'_2 = [0, \infty)$, that should be interpreted as follows: if $v_2 = 0$, then the slope of the objective value is 5 as long as $v_1 \in I'_1$; if $v_1 = 0$, then

Figure 6. Primal degeneracy: the origin of the right-hand side perturbation space is on the boundary of different primal basic cones.

the slope of the objective value is 0 as long as $v_2 \in I_2'$ (Fig. 6).

Thus, in order to get a correct sensitivity analysis, we have to distinguish between positive and negative perturbations. For example, if we increase the first right-hand side coefficient, then interval I_1 applies, and the objective function increases with a rate of 7/2; this rate is sometimes called *right-hand shadow price*. If we decrease the first right-hand side coefficient, then I_1' applies, and the objective function decreases with a rate of 5; this rate is sometimes called *left-hand shadow price*.

Dual Degeneracy

Dual degeneracy usually implies multiple primal optimal solutions, all associated with the same dual solution, that is, with the same slope of the objective function value (see **Degeneracy and Variable Entering/Exiting Rules**). Geometrically, this means that there are multiple and overlapping primal basic cones containing the origin, and that the optimal value function has constant slope on the union of all these cones. To clarify this point, let us modify the objective vector of our toy example:

$$\begin{aligned} \max \quad & 8x_1 + 10x_2 + 7x_3 + x_4 \\ \text{subject to} \quad & x_1 + x_2 + x_3 = 10 \\ & x_1 + 3x_2 + x_4 = 18 \\ & x_1, x_2, x_3, x_4 \geq 0. \end{aligned}$$

One can check that the above model has four distinct primal nondegenerate optimal bases $B(h)$, with $h = 1, 2, 3, 4$. These bases and the corresponding primal solutions are listed below.

h	$B(h)$	p_1^h	p_2^h	p_3^h	p_4^h
1	{1,2}	6	4	0	0
2	{1,4}	10	0	0	8
3	{3,2}	0	6	4	0
4	{3,4}	0	0	10	18

We have

$$\begin{aligned} d^{(h)} &= (c_{B(h)}^T A_{B(h)}^{-1})^T = (7, 1)^T \quad \text{and} \\ c_{N(h)}^T - d^{(h)T} A_{N(h)} &= 0, \end{aligned}$$

for all $h = 1, 2, 3, 4$. Thus, all bases are dual degenerate and share the same dual solution. The optimal objective value is $z^* = 88$. The corresponding four primal basic cones are

$$\begin{aligned} C_P^{(1)} &= \{v \in \mathbb{R}^2 : -(3/2)v_1 + (1/2)v_2 \leq 6; \\ &\quad (1/2)v_1 - (1/2)v_2 \leq 4\}, \\ C_P^{(2)} &= \{v \in \mathbb{R}^2 : -v_1 \leq 10; v_1 - v_2 \leq 8\}, \\ C_P^{(3)} &= \{v \in \mathbb{R}^2 : -v_1 + (1/3)v_2 \leq 4; \\ &\quad -(1/3)v_2 \leq 6\}, \\ C_P^{(4)} &= \{v \in \mathbb{R}^2 : -v_1 \leq 10; -v_2 \leq 18\}. \end{aligned}$$

They are depicted in Fig. 7: notice that the origin is in the interior of every cone. Consider ordinary sensitivity analysis on the first right-hand side coefficient. Depending on the basis returned by the simplex method, four different intervals are obtained:

$$\begin{aligned} I_1^{(1)} &= [-4, 8], I_1^{(2)} = [-10, 8], \\ I_1^{(3)} &= [-4, \infty), I_1^{(4)} = [-10, \infty). \end{aligned}$$

Figure 7. Dual degeneracy: the origin of the right-hand side perturbation space is in the interior of different, overlapping primal basic cones.

Notice that in this case, every interval corresponds to the perturbation of a different primal optimal solution, but the slope of the optimal objective function is always the same.

Some Guidelines

In general, under primal and/or dual degeneracy, the analysis developed for the nondegenerate case is still valid, but the interpretation of its results needs special attention. The following guidelines are useful for a correct interpretation [5].

- The optimal basis is not necessarily unique; the sensitivity analysis results depend on the particular basis used.
- The dual solution gives the rate of change in the objective value if the right-hand side vector is changed within the primal basic cone; the dual solution remains optimal in this cone.
- The primal solution gives the rate of change in the objective value if the objective vector is changed within the dual basic cone; the primal solution remains optimal in this cone.

Such guidelines should be taken into account for ordinary sensitivity analysis,

100% rule, and the tolerance approach, since all return subsets of the basic cones. A particular remark is required by the tolerance approach. Consider again, right-hand side perturbations in the example of primal degeneracy considered above. Recall that the tolerance approach looks for the largest cube centered in the origin and contained in the primal basic cone. It is easy to check that, for both optimal bases B and B' , this cube reduces to the origin itself, thus $\rho^* = 0$. This is true whenever primal degeneracy occurs. Hence, individual tolerances should always be used.

Using Optimal Values

When ordinary sensitivity analysis, that is perturbation in a single coefficient, is considered, then degeneracy issues may be faced more satisfactorily.

Let d be the dual solution associated with the returned optimal basis B . We know that d_i is the slope of the optimal value function in the interval I_i , for all $i \in M$. If dual degeneracy occurs, the slope could remain d_i also on a wider interval. We may identify the widest interval by solving two auxiliary linear programs. Let

$$\begin{aligned} s &= \min_{\beta, x} \{ \beta : Ax - \beta e^{(i)} = b, x \geq 0, \\ &\quad c^T x = z + d_i \beta \}, \\ f &= \max_{\beta, x} \{ \beta : Ax - \beta e^{(i)} = b, x \geq 0, \\ &\quad c^T x = z + d_i \beta \}. \end{aligned}$$

By construction, the slope of the optimal objective value is d_i if and only if $s \leq \beta \leq f$.

Consider now a case of primal degeneracy. Since vector b lies on the boundary of different primal basic cones, the dual optimal solution, and thus the rate of change of the optimal objective value, may change depending on the sign and direction of the perturbation. We may identify the correct dual solutions to use by solving two auxiliary linear programs. Let

$$\begin{aligned} \delta^- &= \min_y \{ y_i : y^T A \geq c^T, y^T b = d^T b \}, \\ \delta^+ &= \max_y \{ y_i : y^T A \geq c^T, y^T b = d^T b \}. \end{aligned}$$

It can be proved [6] that in case of ordinary sensitivity analysis with respect to the i th entry of the right-hand side vector, the correct slopes of the optimal objective value for negative and positive perturbations are respectively, δ^- and δ^+ .

FURTHER READING

Key references on sensitivity analysis are the book by Gal [7] and the succeeding one edited by Gal and Greenberg [8]. An excellent survey on different approaches to sensitivity analysis in linear programming is given by Ward and Wendell [9].

The tolerance approach has been proposed by Wendell [3]. The original idea has been successively extended to exploit *a priori* information in order to enlarge the tolerance intervals and to admit individual tolerances. Other extensions and applications are cited in Ref. 7. The use of tolerance regions beyond the basic cones is considered in Ref. 9.

Often, textbooks do not stress adequately the interpretation problems connected with degeneracy. This fact has been pointed out by some authors, for example, Ref. 10.

Let X^* be the set of optimal solutions of problem (P) . Consider the following sets:

$$\mathcal{B} = \{j \in E : x_j > 0 \text{ for some } x \in X^*\},$$

$$\mathcal{N} = \{j \in E : x_j = 0 \text{ for all } x \in X^*\}.$$

Sets $\mathcal{B}$ and $\mathcal{N}$ form a partition of the index set E , called *optimal partition*. Under mild hypotheses, path-following interior point methods for linear programming return an optimal solution x^* such that

$$\{j \in E : x_j^* > 0\} = \mathcal{B}$$

(see **Central Path and Barrier Algorithms for Linear Optimization**). Starting from this fact, a stream of research has originated on sensitivity analysis founded on the stability of optimal partitions of variables instead of optimal bases [11,12]. The main advantage of optimal partitions is that their analysis is not affected by degeneracy; cases where optimal partitions are useful in practice are illustrated in Ref. 13.

A related approach to sensitivity analysis is founded on the stability of the set of *active constraints*, that is, the set of inequality constraints that remain satisfied as equality in an optimal solution. See Ref. 14 and references therein.

Sensitivity analysis with respect to the matrix A of constraint coefficient is much less studied. We mention again Refs 7 and 8 and the references therein. An approach using optimal partitions is studied in Ref. 15.

Finally, a criticism on the use of sensitivity analysis to couple uncertainty on the parameters of a deterministic linear program is suggested in Ref. 16 and further elaborated in Ref. 17.

SENSITIVITY ANALYSIS OF SIMULATION MODELS

JACK P.C. KLEIJNEN
Department of Information
Management/Center, Tilburg University,
Tilburg, Netherlands

Sensitivity analysis of simulation models quantifies the change in the simulation output as the simulation input changes. Such an analysis may have the following goals:

- verification and validation (V & V)
- optimization
- risk or uncertainty analysis and robustness analysis.

Notice that this contribution will provide many synonyms because the terminology differs among the many scientific disciplines in which simulation is applied [1].

The simulation *output* (say) w may be either a single response (a scalar or univariate variable) or multiple responses (a vector or multivariate variable). This contribution assumes that in case of multiple outputs the sensitivity analysis is applied per output. In linear regression analysis (see the section titled “Classic Designs and Metamodels” below), ordinary least squares (OLS) ignoring the correlations among the multiple outputs suffices (no generalized least squares (GLS) needed) [2, p. 703]. In Kriging (Gaussian process modeling), however, it may be better not to ignore these correlations; see the section titled “Kriging Metamodels and Designs.”

The simulation *input* consists of (say) k input variables x_j with $j = 1, \dots, k$. These inputs may be further classified in different ways. From a *managerial* point of view, Taguchi [3] distinguishes between decision or control variables (e.g., number of machines of each type in manufacturing facility design; see also the section titled “Manufacturing Applications” in this encyclopedia) and environmental or noise factors (e.g., machine

failure rates). Inputs are called *factors* in the statistical theory on design of experiments (DOE). Realistic simulation models have multiple inputs so $k > 1$.

From a *mathematical* point of view, the inputs x_j may be divided into qualitative (nominal, categorical) and quantitative inputs; the quantitative inputs may be further divided into integer (using either an absolute or an ordinal scale) and continuous (interval or ratio scales) [4, p. 11]. The (say) $k' \leq k$ quantitative inputs may be varied either locally or globally (global sensitivity analysis is also called *What If* analysis). Local changes enable the estimation of the *gradient*, which is the vector with the first-order partial derivatives (say) $\nabla(w) = (\partial w/\partial x_1, \dots, \partial w/\partial x_{k'})$, where $w(x_1, \dots, x_{k'})$ denotes the Input/Output (I/O) function (or mapping) implicitly defined by the given simulation model (computer program or code). Gradients play an important role in simulation optimization (see the sections titled “Simulation Optimization” and “Stochastic Approximation Methods” and also the article ***Simulation Optimization in Risk Management*** in this encyclopedia). If the inputs, however, are integers (e.g., number of machines) or qualitative (e.g., priority rule), then the gradient is not defined.

The users may also be interested in output changes caused by *global* changes in an input; that is, an input changes from its minimum to its maximum in the *experimental area*. The selection of this area is not detailed in the DOE literature. This area is called the *experimental frame* in Ref. 5, emphasizing that the given simulation model may be valid for one area, but not for a different area; for example, the model may be valid for a small area concentrated around the current or “base” *scenario*—combination of factor values. The experimental area depends on the *goals* of the simulation study; that is, sensitivity analysis of a proposed completely new system has other requirements than optimization of the current system has. Various goals are discussed in Refs 6 and 7.

Sensitivity analysis is needed for any type of simulation model—be it discrete-event, continuous, or hybrid (see also *Simulation Optimization in Risk Management*), terminating or nonterminating (see *Introduction to Discrete-Event Simulation*). The sensitivity analysis in this contribution uses statistical methods (techniques) that have been developed for the design and analysis of the following three types of experiments:

- real-life (physical) systems
- deterministic simulation models
- random (stochastic) simulation models.

DOE for *real-life* systems is covered extensively by many textbooks [8,9]. DOE for *deterministic simulation* gained popularity with the increased use of “computer codes” for the design (in an engineering, not a statistical sense) of airplanes, automobiles, TV sets, chemical processes, computer chips, and so on—in computer aided engineering (CAE) and computer aided design (CAD). DOE in this domain is often called *design and analysis of computer experiments* (DACE). The classic article on DACE is Ref. 10; a classic textbook is Ref. 11. DOE for *random simulation* is the focus of several textbooks by Kleijnen; the most recent one is Ref. 4.

Note that deterministic simulation models become random if the exact input values are unknown. Hence, these values are sampled from statistical distribution functions. For example, the well-known economic order quantity (EOQ) model assumes that the demand rate is constant and known. In practice, however, the demand rate is unknown, but a distribution function of its possible values may be estimated from past data or from expert opinion. A sample may then be generated from this input distribution and fed into the EOQ model. This input sample is propagated through the EOQ model to generate a sample of values for the output (inventory cost). The resulting estimated density function (EDF) of the output may be analyzed to determine the appropriate decision variable, namely the EOQ. This EOQ example is detailed in Ref. 12. This is related to *risk analysis* discussed in the section titled “Risk Analysis” in this encyclopedia; see also Refs 4,

pp. 3, 123–130. Sensitivity analysis and risk analysis answer different questions. Sensitivity analysis answers the question: “Which are the most important factors in the simulation model of a given real system.” Risk analysis answers the question: “What is the probability of a given event happening: for example, a nuclear or a financial disaster?”

Sensitivity analysis using DOE perceives the simulation model as a *black box*: that is, only the simulation I/O data are used (it ignores the values of internal variables and specific functions implied by the simulation’s computer modules). *White-box* approaches look inside the simulation model (e.g., at service time generated by $-\ln(r)/\mu$) to estimate the gradient for local—not global—sensitivity analysis and for optimization; examples of such white-box approaches are perturbation analysis and the score function or likelihood ratio method. These latter methods require fewer simulation runs, but stricter mathematical assumptions so their application domain is more restricted. Perturbation analysis is detailed in Ref. 14, the score function in Ref. 15; see also Refs 16 and 17, the section titled “Simulation Optimization,” and the article titled *Simultaneous Perturbation and Finite Difference Methods* in this encyclopedia.

Sensitivity analysis through DOE implies a *metamodel* to select an experimental design and to analyze the experimental results; that is, *design* and *analysis* of experiments are like “chicken and egg.” The analysis uses—implicitly or explicitly—a metamodel (also called *response surface*, *surrogate*, *emulator*, etc.), which is an approximation of the I/O function implied by the underlying simulation model; that is, the experiment yields I/O data that are used to estimate this function.

There are different *types* of metamodels. The most popular type are polynomials of first or second order (degree); see the section titled “Classic Designs and Metamodels” below. Obviously, a first-order polynomial implies a gradient that remains constant over the whole experimental area. Another metamodel type are Kriging models, which enable the approximation of more general I/O functions; such a Kriging metamodel implies

a gradient that changes over the whole experimental area, as the section titled “Kriging Metamodels and Designs” will show. References to other metamodel types are given by Kleijnen [4, p. 8].

Different metamodels require different designs; for example, first-order polynomials require two values per factor, whereas Kriging requires many more values per factor—as the following sections will show. The adequacy of the design and metamodel combination depends on the *goal* of the experiment [6].

Thus, sensitivity analysis may also serve *optimization*. Besides the methods discussed in the section titled “Simulation Optimization” in this encyclopedia, there are methods closely related to the methods discussed in this contribution. The latter methods allow multiple random simulation outputs, selecting one output as the goal (objective) output while the other random simulation outputs must satisfy prespecified target values (thresholds). Generalized response surface methodology (GRSM) fits a series of local low-order polynomials to the simulation I/O data [18]. Kriging is combined with integer nonlinear programming in Ref. 19 (see also the section titled “Nonlinear Programming (NLP) and Global Optimization (GO)” in this encyclopedia). “Robust” simulation-optimization in the sense of Taguchi [3] is discussed in Ref. 12.

The *V & V* of simulation models may use expert knowledge; for example, it is well-known that the more customers arrive per time unit, the more their waiting times increase. However, this knowledge is qualitative; to obtain quantitative knowledge, a simulation model is developed. If the simulation model’s I/O behavior violates this qualitative knowledge, the model should be seriously questioned: are there programming and conceptual errors? A case study is the ecological simulation of CO₂ gas emissions in Ref. 20; the regression metamodel leads to the discovery of a computer error (one of the simulation modules should be split into two modules and called in the correct order). Another case study is the sonar simulation in Ref. 21, which consists of several modules. For some modules, the naval experts suggest that the

factors have specific signs; the corresponding estimates in the regression metamodel turn out to have these signs so the validity of these modules does not seem questionable.

Whereas in real-life experimentation it is not practical to investigate many factors, realistic simulation experiments may have hundreds of factors. Moreover, whereas in real-life experiments it is hard to vary a factor over many values, in simulation experiments this restriction does not apply [Latin hypercube sampling (LHS) is a design that has as many values per factor as it has combinations; see the section titled “Kriging Metamodels and Designs” below]; hence, a multitude of scenarios may be observed. Furthermore, simulation experiments are well-suited to the application of sequential designs instead of “one-shot” designs; see the sections titled “Factor Screening: Sequential Bifurcation” and “Kriging Metamodels and Designs” below. Thus, a change of mindset of the experimenter is necessary [22].

The following overview of the remainder of this contribution enables the readers to decide which sections they might wish to skip. Because of space restrictions this contribution aims at enabling the readers to understand the major problems and solutions in sensitivity analysis; for details they need to consult the references.

The section titled “Classic Designs and Metamodels” covers *classic* designs and their corresponding metamodels, namely, Resolution-III (R-III) designs including selected 2^{k-p} designs for first-order polynomials, Resolution-IV (R-IV) and Resolution-V (R-V) designs for two-factor interactions, and designs including central composite designs (CCDs) for second-degree polynomials. Compared with these designs, the traditional approach of changing one factor at a time is inferior; that is, the traditional approach does not enable the estimation of interactions among factors, and it gives less accurate estimators of the first-order effects of the factors [4, p. 33].

The section titled “Factor Screening: Sequential Bifurcation” reviews *factor screening*, focusing on sequential bifurcation.

Table 1. An One-Sixteenth Fractional Factorial Design for Seven Factors

Combination	1	2	3	4 = 1.2	5 = 1.3	6 = 2.3	7 = 1.2.3
1	−	−	−	+	+	+	−
2	+	−	−	−	−	+	+
3	−	+	−	−	+	−	+
4	+	+	−	+	−	−	−
5	−	−	+	+	−	−	+
6	+	−	+	−	+	−	−
7	−	+	+	−	−	+	−
8	+	+	+	+	+	+	+

Traditionally, simulation analysts experiment with only a few factors, assuming that these factors are the most important ones.

The section titled “Kriging Metamodels and Designs” reviews *Kriging* and its designs. Kriging metamodels are fitted to data that are obtained for larger experimental areas than the areas often used when fitting low-order polynomials; that is, Kriging models are *global* rather than local. Kriging is used for prediction; its final goals are sensitivity analysis and optimization.

The last section *summarizes* this contribution.

CLASSIC DESIGNS AND METAMODELS

Let $w(x_1, \dots, x_k)$ denote the *true* I/O function of the given simulation model. Sensitivity analysis using DOE approximates this $w(\cdot)$ through a relatively simple explicit function, which forms a *metamodel* of the underlying simulation model. An example metamodel is the *first-order polynomial* augmented with a residual term:

$$y = \beta_0 + \sum_{j=1}^k \beta_j x_j + \epsilon, \quad (1)$$

where ϵ denotes the *residual*, which is caused by the approximation error (lack-of-fit) of the metamodel plus the noise caused by the pseudo random numbers (PRNs) used in random simulation; β_j quantifies the first-order effect of factor j , which is called the *main* effect in DOE (especially in analysis of variance (ANOVA)); β_0 is the intercept; y is the

metamodel output or predictor of the true simulation output.

To estimate the coefficients of polynomial metamodels, many DOE textbooks give specific designs. To understand these designs, consider an example with $k = 7$ factors. To estimate the first-order polynomial metamodel, at least $k + 1 = 8$ combinations need to be simulated. Table 1 presents a so-called 2^{7-4}_{III} design, which should be read as follows. The columns with the symbols **1** through **7** give the values of factor j ($j = 1, \dots, 7$) in the experiment; **4 = 1.2** means that the value of factor 4 equals the product of the values of the factors 1 and 2 in the corresponding combination the symbol “−” means that the factor has the standardized value -1 —which corresponds with the lowest value in the original scale—and “+” means that the factor has the standardized value $+1$ —highest value in the original scale. For example, the element in row 1 and column **7** is -1 because $x_{1,7} = x_{1,1}x_{1,2}x_{1,3} = (-1) \times (-1) \times (-1)$.

Table 1 is an example of a *R-III design*, which is defined as a design that enables the unbiased estimation of the coefficients of the first-order polynomial—assuming that this polynomial is an adequate or “valid” approximation of the true I/O function. Table 1 specifies only 8 combinations; that is, this design requires the simulation of only a $2^{-4} = 1/16$ fraction of all $2^7 = 128$ combinations that a “full-factorial two-level” design would require.

A R-III design enables the *OLS* estimation of the coefficients of the first-order polynomial

in Equation (1):

$$\hat{\beta} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{w}, \quad (2)$$

where $\hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_k)'$ denotes the OLS estimator, $\mathbf{X}$ the $n \times q$ matrix of explanatory (independent, regression) variables; n the number of factor combinations; q the number of regression coefficients; the estimated intercept $\hat{\beta}_0$ corresponds with a column for the dummy variable (say) x_0 that has the constant value +1 in the experiment. OLS is the classic estimation method in linear regression analysis, assuming *white noise*; that is, the metamodel's residuals ϵ are normally (Gaussian), independently, and identically distributed (NIID) with zero mean.

Note that Equation (1) implies that the most important factor is the one with the maximum absolute value of the first-order effect. The estimated gradient is $(\hat{\beta}_1, \dots, \hat{\beta}_k)'$ if all k factors are continuous.

Next, the *validity* of the fitted first-order polynomial metamodel may be tested. The DOE literature presents an F lack-of-fit statistic, but this test assumes white noise. A more general procedure uses the fitted metamodel to predict the outcome of the given simulation model with an input combination that is not part of the R-III design. An example combination is any of the 2^7 combinations that is not listed in the rows of Table 1; another example is the combination that is the “center” of the experimental area, defined by $x_j = 0$ for all quantitative factors. A 2^{7-4} design is *saturated*; that is, $n = q$ (the OLS estimator defined in Equation (2) still exists). However, if $k = 6$, then Table 1 can still be used but one of the columns (e.g., the last column) is not used. In that case the design is not saturated: $n = 8 < q = 7$. Then the adequacy of the metamodel may be tested through *cross-validation*; that is, row i ($i = 1, \dots, n$) of the design is deleted; the metamodel is reestimated from the remaining $(n - 1)$ combinations; the reestimated metamodel is used to predict the expected simulation output $E(w_i)$; if the resulting prediction error is too big, then the metamodel is rejected [4, pp. 57–63].

If the fitted metamodel is found not to be valid, then an alternative metamodel may

be the first-order polynomial in Equation (1) augmented with *two-factor interactions* $\beta_{j,j'}$:

$$y = \beta_0 + \sum_{j=1}^k \beta_j x_j + \sum_{j=1}^{k-1} \sum_{j'=j+1}^k \beta_{j,j'} x_j x_{j'} + \epsilon. \quad (3)$$

The number of effects now increases dramatically: $q = 1 + k + k(k - 1)/2$; for example, $k = 6$ implies $q = 22$. A *R-IV design* ensures that the estimated first-order effects $\hat{\beta}_j$ are *not biased* by the two-factor interactions $\beta_{j,j'}$. Such a design is easily constructed, as follows. Let $\mathbf{D}$ denote the R-III design; that is, replace the symbol “−” in Table 1 by −1, and “+” by 1 so the 8×7 design matrix $\mathbf{D}$ results. Adding $-\mathbf{D}$ to $\mathbf{D}$ gives a R-IV design (so the R-IV design doubles the number of combinations).

To get unbiased estimators of the *individual* interactions in Equation (3), a *R-V design* is needed. An example is a 2_V^{6-1} design, which can be found in any DOE textbook. Unfortunately, its $2^5 = 32$ combinations may take too much computer time if a simulation run is computationally expensive. In that case, it is better to use a saturated design; for example, a Rechtschaffner design, listed in Ref. 4, p. 49.

Simulation optimization may use a *second-degree polynomial* metamodel

$$y = \beta_0 + \sum_{j=1}^k \beta_j x_j + \sum_{j=1}^k \sum_{j'=j}^k \beta_{j,j'} x_j x_{j'} + \epsilon, \quad (4)$$

so the number of effects further increases with k “purely quadratic” effects $\beta_{j,j}$ —assuming all k inputs are quantitative. To estimate all effects in Equation (4), a *CCD* augments the R-V design with the “central point” and $2k$ “axial points,” which change each factor one-at-a-time by $-c$ and c units where $c > 0$. Unfortunately, a CCD is rather wasteful in case of expensive simulation models, because it uses five values per factor (instead of the minimum three needed to estimate a second-order polynomial) and it is not saturated. Alternatives for CCDs are discussed in Refs 4 and 9.

Many simulation applications of these classic designs are provided by Ref. 4.

This reference also discusses multivariate simulation outputs, nonnormality of the output, variance heterogeneity, and common random numbers (CRN) (also see **Common Random Numbers**).

FACTOR SCREENING: SEQUENTIAL BIFURCATION

The *goal* of factor screening is to identify the really important factors among the many factors that may be varied in a simulation experiment. Realistic simulation models may have hundreds or thousands of factors. Unfortunately, many simulation analysts vary only a handful of factors, conjectured to be the most important ones. Screening is related to “sparse” effects, “parsimony,” “Pareto principle,” “Occam’s razor,” “20–80 rule,” and “curse of dimensionality.”

The need for screening is illustrated by the following two case studies. In Ref. 23, a greenhouse deterministic simulation model has 281 factors; Dutch politicians, however, want to reduce the release of CO₂ gasses, starting with legislation for a few factors only. In Ref. 24, a discrete-event simulation model of a supply chain of the Ericsson company in Sweden has 92 factors; screening identifies a shortlist with 10 factors after simulating only 19 combinations.

There are several *types* of screening designs. R-III designs (already discussed in the section titled “Classic Designs and Metamodels”) are called *screening designs* by some authors [25]. Actually, simulation experiments proceed sequentially (ignoring parallel computers), so it is possible to apply designs that sequentially select factor combinations to be simulated. Sequential bifurcation is an efficient design—it is *super-saturated*; that is, $n < k$ —and it is effective if the following metamodel *assumptions* are satisfied (see also [26]):

1. a first-order polynomial augmented with two-factor interactions—see Equation (3)—is an adequate approximation;
2. all its first-order effects β_j have known signs and are nonnegative;
3. it shows “strong heredity”; that is, if a factor has no important main effect (e.g., $\beta_1 = 0$), then this factor does not interact with any other factor ($\beta_{1:j} = 0$) [27].

The role of these assumptions may be demonstrated as follows. The first step of sequential bifurcation aggregates all factors into a single group, and tests whether or not that group of factors has an important effect; that is, combination 1 has $x_j = -1$ ($j = 1, \dots, k$) and combination 2 has $x_j = 1$. Substitution of these x values into Equation (3) proves that *no cancellation* of effects occurs, given assumption 2. If that group indeed has an important effect—which is very likely in the first step—then the second step splits the group into two subgroups—it bifurcates—and tests each of these subgroups for importance. In the next steps, sequential bifurcation splits important subgroups into smaller subgroups, and discards unimportant subgroups. In the final step, all individual factors that are not in subgroups identified as unimportant, are estimated and tested. Details are given in Ref. 28, including references to alternative sequential screening methods.

KRIGING METAMODELS AND DESIGNS

Originally, the South African mining engineer Danie Krige developed Kriging (also spelled as *kriging*) for interpolation in geo-statistical or spatial sampling; see the classic Kriging textbook [29]. Later on, Kriging was applied to the I/O data of deterministic simulation models [10,11]. Only recently, Kriging has also been applied to random simulation models; see the references below.

So-called *Ordinary* Kriging uses the *linear* predictor

$$y = \lambda' \mathbf{w}, \quad (5)$$

where $\mathbf{w}$ denotes the vector with the n “old” simulation outputs (assuming no replicates, which is indeed the case for deterministic simulation) and λ denotes the vector with Kriging weights. Under the assumption that

the outputs form a stationary covariance process, the *optimal Kriging weights* are

$$\lambda_o = \Gamma^{-1} \left(\gamma + 1 \frac{1 - \mathbf{1}' \Gamma^{-1} \gamma}{\mathbf{1}' \Gamma^{-1} \mathbf{1}} \right), \quad (6)$$

where $\gamma = (\text{cov}(w_i, w_{i'}))$ with $i, i' = 1, \dots, n$ denotes the $n \times n$ matrix with the covariances between the n old outputs, and $\gamma = (\text{cov}(w_i, w_{n+1}))$ denotes the n -dimensional vector with the covariances between the n old outputs w_i and the “new” output w_{n+1} to be predicted. Obviously, γ varies with the location of this new output, so these weights λ_o are not constants (the regression parameters β are). Kriging assumes that outputs are more correlated, the closer their inputs are. Actually, the most popular type of *correlation function* in Kriging of simulation I/O data is

$$\exp \left(- \sum_{j=1}^k \theta_j h_j^{p_j} \right) = \prod_{j=1}^k \exp \left(- \theta_j h_j^{p_j} \right), \quad (7)$$

where h_j denotes the Euclidean distance between the j th input x_j ($j = 1, \dots, k$) of the input combinations $\mathbf{x}_g$ and $\mathbf{x}_{g'}$ ($g, g' = 1, \dots, n+1$); θ_j denotes the importance of input j (the higher θ_j is, the less effect input j has), and p_j denotes the smoothness of the correlation function (e.g., $p_j = 2$ implies an infinitely differentiable function); $p = 1$ and $p = 2$ give the so-called *exponential* and *Gaussian correlation* functions, respectively. So, the correlation function (Eq. 7) implies that the weights (Eq. 6) decrease with the *distance* between the new input combination to be predicted $\mathbf{x}_{n+1}$ and the n old combinations $\mathbf{x}_i$.

The resulting Kriging predictor is an *exact interpolator*; that is, the Kriging predictions equal the outputs observed for the n old input combinations ($y_i = w_i$; $i = 1, \dots, n$). This is an attractive property in deterministic simulation, but not in random simulation. Only recently, Kriging has been investigated for random simulation models; the oldest publication seems [30]. Furthermore, Ref. 11, pp. 215–249 accounts for the so-called *nugget effect* or *measurement error* such that the Kriging predictor does not interpolate the n

old outputs. Recently, Ankenman *et al.* [31] introduced Kriging for random simulation, accounting for variance heterogeneity (e.g., the variance of the waiting time increases as the traffic rate in a queueing simulation increases). A similar Kriging model is developed by Yin *et al.* [32], speaking of the “modified nugget effect.” The Kriging predictors that account for nugget effects do not interpolate $\bar{w}_i$, the outputs averaged over the (say) $m_i \geq 1$ ($i = 1, \dots, n$) replicates per input combination. Finally, Ankenman [31] accounts for possible correlations between the outputs for different input combinations caused by CRN.

It can be shown that the Kriging meta-model resulting from Equations (5) and (6) implies a specific *gradient*; see Ref. 4, p. 156 (software provides these gradients; see next paragraph).

A major problem is that *the correlation function is unknown*, so both the type and the parameter values must be estimated; see again Equation (7). To estimate the parameters, the standard Kriging literature and software uses maximum likelihood estimators (MLEs). The estimation of the correlation functions, the corresponding optimal Kriging weights, the Kriging predictor, and the corresponding gradient in deterministic simulation can all be done through DACE, which is Matlab software that is well documented and free of charge [33]. Unfortunately, for random simulation there is no well-documented software yet; so, in the mean time, Kriging might apply DACE to the averages $\bar{w}_i$. For example, van Beers and Kleijnen [30] uses DACE with these averages, and reports Kriging predictions that are much better than regression predictions.

The Kriging literature virtually ignores problems caused by replacing the optimal weights λ in Equation (5) by the estimated optimal weights (say) $\hat{\lambda}_0$; see Equation (6) or a related formula that accounts for nugget effects and CRN. These estimated weights make the Kriging predictor a *nonlinear* estimator. Consequently, the literature underestimates the true variance of the Kriging predictor; moreover, this estimated variance

and the true variance do not reach their maxima for the same input combination, which is important in sequential designs [34].

There is a simple solution to this variance estimation problem, in random simulation if each input combination is replicated a number of times; this solution is *distribution-free bootstrapping*. The basics of bootstrapping are explained in Ref. 35. In Kriging, the bootstrap resamples with replacement the m_i replicates for combination i ($i = 1, \dots, n$). This sampling gives the bootstrapped average $\bar{w}_i^*$ where the superscript $*$ is the usual symbol to denote a bootstrapped observation. These n bootstrapped averages $\bar{w}_i^*$ give the bootstrapped estimated weights λ_0^* using a formula like Equation (6) with $\hat{\Gamma}^* = (\widehat{cov}(\bar{w}_i^*, \bar{w}_{i'}^*))$ with $i, i' = 1, \dots, n$ and $\hat{\gamma}^* = (\widehat{cov}(\bar{w}_i^*, \bar{w}_{n+1}^*))$. Then, Equation (5) gives the bootstrapped Kriging predictor $y^* = \lambda_0^* \bar{\mathbf{w}}^*$. This predictor gives the bootstrapped gradient $\nabla(w)^*$. To decrease sampling effects, this whole procedure is repeated B times (e.g., $B = 100$). This enables estimation of the mean and variance of the Kriging predictor and its gradient [36].

To obtain the Kriging I/O simulation data, experimenters often use LHS. LHS gives a space-filling design that is *noncollapsing*; that is, projection of a point in the k -dimensional input space onto one of the k axes gives a uniform spread on that axis. Different types of LHS and other types of space-filling designs (including references and software) are discussed in Ref. 4, p. 130.

Instead of a (one-shot) design like LHS, a *sequentialized* design may be used. In sensitivity analysis of simulation models, a sequential design implies that the simulation I/O data are analyzed—so the data generating process is better understood—*before* the next input combination is selected. This property implies that the design depends on the specific underlying simulation model; that is, the design is customized (tailored or application-driven, not generic). Moreover, simulation proceeds sequentially (again ignoring parallel computers) so sequential designs are attractive. The following sequential design for Kriging in sensitivity analysis is developed in Ref. 36:

1. Start with a *pilot* experiment, using some small generic space-filling design (e.g., LHS).
2. Fit a *Kriging* metamodel to the simulation I/O data that are available at this step (in the first pass of this procedure, these data are the data resulting from step 1).
3. Consider (but do not yet simulate) a set of *candidate* input combinations that have not yet been simulated and that are selected through some space-filling design; select as the next combination to be actually simulated, the candidate combination that has the *highest predictor variance* (estimated through bootstrapping).
4. Use the combination selected in step 3 as the input combination to be simulated, and obtain the corresponding simulation output.
5. Refit a Kriging model to the I/O data augmented with the data from step 4.
6. Return to step 3, until the Kriging metamodel is acceptable for its goal, sensitivity analysis.

The resulting design is indeed *customized*; for example, if the true (unknown) I/O function is a simple hyperplane within a subspace of the total experimental area, then this design selects relatively few points in that part of the input space. (A sequential design for constrained optimization—instead of sensitivity analysis—is presented in Ref. 19.)

Nearly all Kriging publications and software assume univariate output, whereas in practice simulation models have *multivariate output*; the latter output is discussed in Ref. 11 [pp. 101–116], 37 and 38. In practice, univariate Kriging is applied per type of simulation output.

Often the analysts know that the simulation's I/O function has certain properties, for example, as the traffic rate increases, the expected waiting time increases monotonically. *Monotonicity-preserving* bootstrapped Kriging is discussed in Ref. 39.

SUMMARY

This contribution gave an overview of sensitivity analysis through the statistical design and analysis of experiments, treating the simulation model as a black box.

It covered classic designs and their analysis through corresponding metamodels; namely, R-III designs for first-order polynomials, R-IV and R-V designs for two-factor interactions, and designs such as CCD for second-degree polynomials.

It also reviewed factor screening for simulation experiments with very many factors, focusing on sequential bifurcation.

Furthermore, it reviewed Kriging and its designs—especially LHS and sequential designs.

Now the challenge is to apply these methods to simulation in practice.

SEQUENTIAL DECISION PROBLEMS UNDER UNCERTAINTY

CHELSEA C. WHITE III
School of Industrial and Systems
Engineering, Georgia Institute
of Technology, Atlanta,
Georgia

We consider in this article, sequential decision problems under uncertainty. We list their general features, discuss how they can be described mathematically, describe what constitutes a practical solution, discuss how the solution can be obtained, and mention several variations of the standard problem statement.

Consider a *system* that evolves between multiple *decision epochs*. At each decision epoch, an *action* (or decision) is selected based on the system's current *state*, and a reward is generated that depends on both the current state and action. The system state then makes transition (*system dynamics*) to a new state at the next decision epoch, and this transition is affected by both the current state and action. The next decision epoch arrives, and the process continues till the end of the *planning horizon*. The current action selected has both immediate impact (e.g., the reward of making the decision) and long-term impact (e.g., the impact on the system state at the next decision epoch). The *problem objective* is to maximize the *problem criterion*, a measure of value that can depend on the values of the states and actions at decision epochs over the planning horizon. A rule that selects an action based on the system's state is called a *policy*. An *optimal policy* is a policy that maximizes the criterion with respect to all (feasible) policies. A *problem solution* is an optimal policy and the value of the concomitant criterion.

For example, consider a camera store that is open for business Monday through Saturday. Inventory is counted each Saturday at the end of the work day, an order is placed to a wholesaler, and the order

arrives Monday, just as the store opens. Customers arrive through the week to make purchases. A wholesale cost is accrued when cameras are ordered; reward is accrued when a camera is sold, and holding costs are accrued for cameras that are not sold. Our objective is to maximize the average profit (reward minus cost) that we can expect to receive over a week's time by selecting the best number of cameras to order, based on current inventory count. Ordering too few cameras reduces immediate wholesale cost but may cause the inventory to stock out, reducing expected profits. Ordering too many cameras will increase immediate wholesale cost and inventory holding cost associated with the cameras that are unsold by the end of the week. Further examples of sequential decision problems under uncertainty, including routing and scheduling, finance, health care, and communications network management, can be found in Refs 1–3.

All models of sequential decision making under uncertainty have the following key ingredients:

- a set of decision epochs;
- a problem horizon;
- a set of actions;
- a definition of state;
- a definition of state observation;
- a definition of what the decision maker knows and when these data become known (called the *information pattern*);
- a description of the dynamics of the system, that is, how the state of the system evolves between decision epochs, as a function of current state and action taken;
- a value structure dependent on action and state values over the problem horizon.

Referring to the camera inventory example:

- Decision epochs occur each Saturday evening.

- Although not explicitly stated above, we will assume that the planning horizon is infinite and hence contains a countable but infinite number of decision epochs.
- The set of actions is the number of cameras that can be ordered each Saturday evening, that is, $\{0, 1, 2, \dots\}$.
- The state is the inventory level, a number in the state space $\{0, 1, 2, \dots\}$, assuming backordering is not allowed.
- We have implicitly assumed that inventory level is perfectly observed at each decision epoch (perfect observations).
- We assume that the decision maker knows the state of the inventory at each decision epoch, past and present (perfect memory).
- We assume that next Saturday's inventory level is the sum of this Saturday's inventory level and the number of items ordered, minus the number of customers who will purchase cameras through the week. In order to insure that our problem is well defined, we assume to know the probability the number of customers who will enter the store through the coming week and make a purchase. Thus, if D is the (random) number of purchases made during the week, then we assume that the probability $\text{Prob}\{D = d\}$ is given for all $d \in \{0, 1, 2, \dots\}$.
- The problem criterion is the expected profit (reward minus cost) per week, where there is a cost per item of ordering wholesale, and inventory holding cost per item for an item in inventory that is not sold, and a reward received when a camera is sold.

For our camera inventory example, a policy is a rule that determines the number of cameras to order and that this number can depend on how many cameras are currently in inventory. An optimal policy, which may not be unique, is a policy that maximizes expected weekly profit. A solution is an optimal policy and the resulting maximum expected weekly profit. At an operational level, an optimal policy tells the decision maker the number of cameras to order

each Saturday, as a function of the current inventory level. Strategically, knowing the maximum expected weekly profit is valuable if deciding whether the company is worth purchasing, assuming the camera store were for sale.

An alternative criterion is the expected total discounted cost over a finite or infinite horizon. In this case, we may need to specify a *discount factor*, which relates the value of a unit of money received at the current decision epoch to the value of a unit of money received at the next decision epoch.

We now explore the various ingredients of a model of sequential decision making under uncertainty in more detail.

Decision Epochs and Problem Horizons. Decision epochs occurred periodically (weekly) in the camera inventory problem, and the planning horizon is infinite. For the general model, decision epochs can also occur when a particular event occurs. For example, the assignment of an incoming job to a set of available machines occurs when the incoming job arrives. Further, the problem of hiring an administrative assistant [i.e., the secretary problem [4]] depends on when applications are received and when subsequent interviews can be scheduled.

The problem horizon can be finite or infinite. Typically, for a problem horizon of length T , the decision epochs are the set $\{1, 2, \dots, T\}$. Throughout, we limit our discussion to a countable number of decision epochs over the length of the problem horizon; see [1], Chapter 11, for a discussion of continuous time models. We also remark that T may be a random variable, as would be the case for optimal stopping problems. Such problems are concerned with choosing a time or decision epoch to take a particular action, such as the secretary problem.

Actions. Let $\mathbf{A}(i)$ be the set of actions available for selection at any decision epoch, given that the state of the system is i . For the camera inventory problem, $\mathbf{A}(i) = \{0, 1, 2, \dots\}$ for all levels of inventory i . In general, the set $\mathbf{A}(i)$ can be finite, countable and infinite, or uncountable. We let $a(t)$ be the action taken at epoch t .

State and State Dynamics. The state of the system is the information that one needs to know about the system in order to intelligently select a good action. For example, in order to intelligently place an order for more cameras, the decision maker needs to know how many cameras are currently in stock. We remark that the level of the camera store's inventory (the state) is dynamic. If $s(t)$ is the inventory level at epoch t , then state dynamics can be described by the equation $S(t+1) = \max\{0, s(t) + a(t) - D(t)\}$, where $S(t+1)$ is the random variable describing the inventory level at epoch $t+1$, $a(t)$ is the number of cameras ordered at epoch t and the random variable $D(t)$ is the number of cameras bought between epochs t and $t+1$.

In general, the dynamics of the state can be described by the stochastic difference equation $S(t+1) = f(s(t), a(t), D(t))$, where $D(t)$ is a random variable with given cumulative distribution function $\text{Prob}\{D(t) \leq d\}$. An alternative description of state dynamics is the conditional probability $\text{Prob}\{s(t+1) = j | s(t) = i, a(t) = a\}$.

Occasionally, other descriptions of state dynamics are given, such as set inclusion, for example, $S(t+1) \in \alpha(s(t), a(t), D(t))$, where $\alpha(s, a, D)$ is a given set dependent on the triple s, a, D . For example, let $s(t)$ be the cost of a barrel of oil at time t . Then, the statement "the cost of a barrel of oil a week in the future is within plus or minus \$10 of the current cost of a barrel of oil" can be described as $s(t) - 10 \leq S(t+1) \leq s(t) + 10$.

State Observations. The camera store example assumes that current inventory can be counted perfectly without cost. Inventory levels for large inventories, however, are not necessarily known accurately. More generally, there are many other examples of systems where the system's state is observed inaccurately and/or a state observation, perfect or imperfect, is costly. For example, any system that involves diagnosis would fall into this category, such as problems involving machine maintenance and repair and human diagnosis and treatment. With regard to the latter example, data available to the decision maker (a health-care provider) are signs, symptoms, and laboratory test results, rather than the actual underlying state of

the patient's health. As another example with an underlying network structure, consider traffic congestion monitoring. Sensors monitor traffic speed and variability, sensor data are transmitted to a traffic control center, and the level of traffic congestion is then inferred. For this example and for the diagnostic examples, corrupted state observations can result from sensor error and data transmission error.

There are two general ways of taking into account state observation error. Let $z(t)$ be the observation of the state available to the decision maker. When state dynamics are described by conditional probability, it is typically assumed that probabilities of the form $\text{Prob}\{Z(t+1) = z, S(t+1) = j | s(t) = i, a(t) = a\}$ are given. Note that

$$\begin{aligned} \text{Prob}\{Z(t+1) = z, S(t+1) = j | s(t) \\ = i, a(t) = a\} &= \text{Prob}\{Z(t+1) = z | s(t+1) \\ &= j, s(t) = i, a(t) = a\} \\ \text{Prob}\{S(t+1) = j | s(t) = i, a(t) = a\}, \end{aligned}$$

where $\text{Prob}\{Z(t+1) = z | s(t+1) = j, s(t) = i, a(t) = a\}$ is referred to as the observation probability and $\text{Prob}\{S(t+1) = j | s(t) = i, a(t) = a\}$ is referred to as the transition probability. We remark that it is usually assumed that $\text{Prob}\{Z(t+1) = z | s(t+1) = j, s(t) = i, a(t) = a\}$ is independent of $s(t) = i$.

If functional equations describe system dynamics, it is typically the case that observations also are described functionally. Hence, $S(t+1) = f(s(t), a(t), D(t))$ and $Z(t+1) = g(s(t+1), s(t), a(t), D'(t))$, where $D(t)$ and $D'(t)$ are random variables with given distribution functions. For a system with state and action spaces having finite cardinality, the conditional distribution description and the functional description of state dynamics are equivalent.

We mention another description of dynamic systems involving corrupted state observations that often has an implicit notion of state: AND/OR tree. The AND/OR tree is usually associated with decision analysis or heuristic search, an area of artificial intelligence (AI). We remark that "heuristic" has different meanings in the operations

research and AI literatures. OR nodes are called *decision nodes* and AND nodes are *consequence* (or “nature’s”) *nodes*. An OR node is the root node, AND nodes follow OR nodes, and OR nodes (other than the root node) follow AND nodes. Each link from an OR node to an AND node is associated with an action $a(t)$, and each link from an AND node to an OR node is associated with an observation $z(t+1)$.

Information Pattern. The information pattern is a description of what the decision maker knows and when the decision maker knows it. It is typically assumed that when a decision epoch occurs, the decision maker knows the current state of the system without delay. It is generally assumed that the decision maker has perfect memory. Hence, actions at epoch t are made, based on the information set $I(t)$, which comprises all past and present observations, $z(1), \dots, z(t)$, all former actions, $a(1), \dots, a(t-1)$, and the *a priori* $\text{Prob}\{s(1) = i\}$, for all i . If the system is completely observed, $s(t)$ serves as a *sufficient statistic* for $I(t)$. That is, knowing $s(t)$ is sufficient for action selection, relative to knowing $I(t)$. For the partially observed case, $x(t)$ is a sufficient statistic, where the i th element of the vector $x(t)$ is the conditional probability $\text{Prob}\{S(t) = i | I(t)\}$.

Policy. A policy is a function that maps $I(t)$ into the action set at epoch t . Thus, policy π chooses action $a(t)$ as follows: $\pi(I(t)) = a(t)$.

Criterion. Let $r(s(1), a(1), \dots, s(T), a(T))$ be the (scalar) reward that we would like to maximize. The value of this reward for policy π and given initial state $s(1)$ is $r(s(1), \pi(I(1)), S(2), \pi(I(2)), \dots, S(T), \pi(I(T)))$. We note, however, that since the $S(t)$ and the $\pi(I(t))$ are random variables for $t \geq 2$, the reward is a random variable. There are several ways of comparing two random variables; we mention two. First, map each random variable into a scalar, such as the maximum (or minimum) the random value can take or the expectation of the reward. We then prefer the larger of the resulting scalar values. Second, compare two random variables using their cumulative probability distributions. For example, let $R = r(s(1), \pi(I(1)), \dots, S(T), \pi(I(T)))$ and $R' = r(s(1), \pi'(I(1)), \dots, S(T),$

$\pi'(I(T)))$. We prefer π to π' if and only if $\text{Prob}\{R' \leq r\} \leq \text{Prob}\{R \leq r\}$ for all r . By far, the most examined criterion is the expectation of the reward.

We remark that the reward function can assume many specialized functional forms. The two most examined are the additive form

$$r(s(1), a(1), \dots, s(T), a(T)) = \sum r(s(t), a(t))$$

and the multiplicative form

$$r(s(1), a(1), \dots, s(T), a(T)) = \prod r(s(t), a(t)).$$

Both of these forms represent appropriate model structure for a variety of real world applications and enable computational simplification.

Problem Objective. Our objective is to determine an optimal policy, that is, a policy that generates a “best” criterion, justifying the above discussion on how two random variables can be compared. Assume, for example, that $v(\pi) = E[r(s(1), \pi(I(1)), \dots, S(T), \pi(I(T)))]$, where E is the expectation operator [conditioned on the initial state value, $s(1)$], and assume that we prefer π to π' if and only if $v(\pi) \leq v(\pi')$. Then, the problem objective is to find a π^* , an optimal policy, such that $v(\pi) \leq v(\pi^*)$, for all policies π . Under a robust set of circumstances, there exists an optimal policy; see [1] for details.

We also remark that both π^* and $v(\pi^*)$ are of interest. An optimal policy is a set of IF-THEN rules that tells the decision maker what actions to take under what circumstances and when [i.e., IF $I(t)$ is the information set at epoch t , THEN $\pi^*(I(t))$ is an action to select]. The scalar $v(\pi^*)$ informs the decision maker what the expected reward will be, assuming actions taken are based on an optimal policy. If this scalar is too low, then the decision maker may decide, for example, to raise prices or find ways to lower costs, or to make a more strategic decision to leave or not enter the business.

Complications can arise when the problem horizon is infinite. An example of such a problem is when $v(\pi)$ is infinite for all π . In this situation, it is typically the case where

total (bounded) costs are discounted by a discount factor strictly less than 1, insuring that $v(\pi)$ for all π is finite if $r(s, a)$ is uniformly bounded. Another approach, assumed in the camera inventory example, is for the criterion to be the average expected value accrued between epochs.

Problem Solution Determination. Thus far, we have described a mathematical model of a generic sequential decision problem under uncertainty. If the model is a reasonably accurate description of the real problem, the problem solution, if known, would be of value to the decision maker. We now show how to determine an optimal policy and the value of the concomitant criterion.

While determining a problem solution, it is an immense help if the criterion is either additive or multiplicative. If so, then the so-called *principle of optimality* can be invoked and a standard application of *dynamic programming* can be used to essentially decompose the problem into a series of single decision epoch problems [5]. Thus, the problem of determining π^* from the set of all policies is equivalent to determining what action to select at epoch t , as a function of $s(t)$, from the set of all available actions, for all t starting at T (when T is finite) and working backward to 1 (which is why this application of dynamic programming is sometimes referred to as *backwards dynamic programming*). This decomposition is referred to as *value iteration* [6]. In the parlance of decision analysis, dynamic programming and *folding back the tree* are equivalent [7]. Although somewhat different in concept, the AI-based algorithms A^* and AO^* also have analogies to dynamic programming [8].

When T is infinite and the criterion is either the expected total discounted reward or the expected average reward, the existence of an epoch-invariant optimal policy is guaranteed when the function $r(s, a)$ is epoch invariant. *Modified policy iteration* [1] is a set of computational procedures for determining an optimal policy and criterion value in this case. These procedures are distinguished by an index $k \in \{1, 2, \dots\}$, where when $k = 1$, modified policy iteration is also called *value iteration*, and when k approaches infinity,

modified policy iteration is called *policy iteration*. *Linear programming* can also be used to find a problem solution.

Structured Results. We remark that certain classes of problems have optimal policies with computationally favorable and easily implemented structural characteristics. For example, consider the camera inventory example. Under very robust circumstances, there exists an optimal policy of the form $\pi(s(t)) = \max\{s^* - s(t), 0\}$, where s^* is an “order up to” inventory number. Note that the problem is now reduced to finding the scalar s^* . Note also that the rule “order up to s^* ” is easy to understand and hence implement.

Many maintenance problems are such that it is optimal to let the machine produce when the “state” of the machine (e.g., a measure of the machine’s capacity to produce quality products) is above a particular threshold and replace the machine once its state has deteriorated below this threshold.

There exists an optimal (s, S) policy for a broad class of inventory problems that require a setup charge before delivery, where one orders up to S if the inventory falls below s ($s \leq S$). Thus, the problem is reduced to finding s and S . Further details can be found in Ref. 1.

The multiarmed bandit problem [9] requires the decision maker to decide at each decision epoch which one of several levers to pull on a multiarmed slot machine in order to maximize expected total discounted reward. A reward is accrued each time a lever is pulled, based on an initially unknown distribution associated with that particular lever. With each pull, the distribution of the selected lever is better identified. The trade-off is between pulling levers with high expected payoffs and learning more about the distributions of the other levers. We also assume that at any decision epoch, the decision maker can quit the game. Under robust assumptions, there exist optimal policies having the form of an index rule: if lever i has the highest index, relative to the indices of the other levers, and if its index is larger than the retirement reward, then pull lever i . If the highest index for all levers is less than the retirement reward, then stop.

Hence, this problem is a type of optimal stopping problem.

Violations of the Principle of Optimality. We remark that if the criterion is a weighted sum of an additive functional form and a multiplicative functional form, the principle of optimality may not hold and hence standard application of dynamic programming algorithms may not be guaranteed to produce an optimal problem solution. Such a situation is of interest since additive criteria are often used to model cost and multiplicative criteria can be used to model risk. Thus, if there is a trade-off of cost and risk under consideration (as might be the case in disruption management or hazardous materials transport routing), then problem solution determination can require specialized algorithms; see [10] for details.

Problem Variations. There are many interesting variations on the standard problem described above, and these variations produce interesting analytical challenges.

Throughout, we have assumed a single decision maker. However, multiple decision makers may exist, each having its own unique information pattern. If each decision maker has its own criterion and is essentially competing with the others, then this is a *game*. If each decision maker is trying to minimize the same criterion, then this is a *team*.

A decision maker may be trying to maximize several criteria simultaneously, which becomes a multiobjective problem [11] in which the problem objective often becomes one of determining the set of *noninferior* policies.

Models of sequential decision problems under uncertainty require an immense amount of precisely specified parameters. In reality, many of the parameters may not be precisely known. For example, $r(s, a)$ may depend on a parameter λ , where all we know is that $\lambda \in \Lambda$. This results in a *parametric problem*, which poses many interesting computational challenges.

We have assumed throughout that the state, or an observation of the state, is available to the decision maker without delay. However, in reality, especially when the system state is measured by sensors,

there are invariable (noise corrupted) data transmission and analysis *delays* that may compromise the *value of information*. An analysis of the value of information, as a function of delay and observation quality, can be found in Ref. 12.

Determining the solutions of problems with large state and action spaces can be computationally challenging. Interesting new techniques for solving such problems can be found in Ref. 13.

INTRODUCTION

We consider the nonlinear, constrained optimization problem to minimize an objective function f under m nonlinear inequality constraints, that is,

$$\begin{aligned} &\text{minimize } f(x) \\ &x \in \mathbb{R}^n : g(x) \geq 0, \end{aligned} \quad (1)$$

where x is an n -dimensional parameter vector and where $g(x) := (g_1(x), \dots, g_m(x))^T$, that is, we have m nonlinear inequality constraints. Equation (1) is now called a *nonlinear program* (NLP) in abbreviated form.

Equality constraints and simple bounds for the variables are omitted to simplify the subsequent notation. They are easily introduced again whenever needed, where equality constraints are linearized in the quadratic programming subproblem. It is assumed that the objective function $f(x)$ and m constraint functions $g_1(x), \dots, g_m(x)$ are continuously differentiable on the whole $\mathbb{R}^n$.

Optimization theory for smooth problems is based on the Lagrangian function that combines the objective function $f(x)$ and the constraints $g(x)$ in a proper way. In particular, the Lagrangian function allows us to state necessary and sufficient optimality conditions.

Let problem (1) be given. First we define the *feasible region* P as the set of all feasible solutions

$$P := \{x \in \mathbb{R}^n : g(x) \geq 0\}. \quad (2)$$

and the set of *active constraints* with respect to $x \in P$ by

$$I(x) := \{j : g_j(x) = 0, 1 \leq j \leq m\}. \quad (3)$$

The *Lagrangian function* of Equation (1) is defined by

$$L(x, u) := f(x) - u^T g(x) \quad (4)$$

for all $x \in \mathbb{R}^n$ and $u = (u_1, \dots, u_m)^T \in \mathbb{R}^m, u \geq 0$. The variables u_j are called the *Lagrangian multipliers* of the nonlinear programming problem. x is also called the *primal* and u the *dual* variable of the NLP (1).

The first idea has been investigated in the Ph.D. thesis of Wilson [1]. Sequential quadratic programming (SQP) methods became popular during the late 1970s due to the articles of Han [2,3] and Powell [4,5]. Their superiority over other optimization methods known at that time, was shown by Schittkowski [6]. Since then many modifications and extensions have been published on SQP methods. Nice review articles are given by Boggs and Tolle [7] and Gould and Toint [8]. All modern optimization textbooks have chapters on SQP methods, for example, see Fletcher [9], Gill *et al.* [10] and Sun and Yuan [11]. As the presentation of even a selected overview is impossible due to the limited space here, we concentrate on a few important facts and highlights from a personal view without any attempt to be complete.

The basic ideas of SQP methods are found in the section titled “Sequential Quadratic Programming Methods.” The role of quasi-Newton updates is outlined in the section titled “Reduced Hessian SQP Steps.” Several stabilization procedures are available by which convergence is guaranteed, for example, line search, which is

discussed in the section titled “Stabilization by Line Search,” trust regions is discussed in the section titled “Stabilization by Trust Regions,” or refer to filter techniques outlined in the section titled “Stabilization by a Filter,” Some typical convergence results for global convergence, that is, convergence toward a stationary point starting from an arbitrary point, and local convergence, fast final convergence speed close to a solution, are listed in the section titled “Convergence.”

SEQUENTIAL QUADRATIC PROGRAMMING METHODS

Sequential quadratic programming or SQP methods belong to the most powerful optimization algorithms we know today for solving differentiable NLPs of the form (1). The theoretical background is described, for example, in Stoer [12], and an excellent review is given by Boggs and Tolle [7]. From a more practical point of view, SQP methods are also introduced in the books of Papalambros and Wilde [13] and Edgar and Himmelblau [14], among many others. Their excellent numerical performance has been tested and compared with other methods, see Schittkowski [6], and for many years they belonged to the set of most frequently used algorithms for solving practical optimization problems.

The basic idea is to formulate and solve a quadratic programming subproblem in each iteration, which is obtained by linearizing the constraints and approximating the Lagrangian function $L(x, u)$ (4) quadratically. Starting from any $x_0 \in \mathbb{R}^n$, suppose that $x_k \in \mathbb{R}^n$ is an actual approximation of the solution, $v_k \in \mathbb{R}^m$ an approximation of the multipliers, and $B_k \in \mathbb{R}^{n \times n}$ an approximation of the Hessian of the Lagrangian function, $k = 0, 1, 2, \dots$. Then, a quadratic program (QP) of the form

$$\begin{aligned} & \text{minimize } \frac{1}{2} d^T B_k d + \nabla f(x_k)^T d \\ & d \in \mathbb{R}^n : \nabla g(x_k)^T d + g(x_k) \geq 0 \end{aligned} \quad (5)$$

is formulated and solved in each iteration. To simplify the subsequent presentation, we assume that (Eq. 5) is always solvable. Let d_k

be the optimal solution, u_k the corresponding multiplier of this subproblem. A new iterate is then obtained by

$$x_{k+1} := x_k + d_k \quad (6)$$

and, for the moment, $v_{k+1} := u_k$.

To motivate the above approach, let us assume that there are only equality constraints of the form $g(x) = 0$. The Karush-Kuhn-Tucker (KKT) optimality conditions are then written in the form

$$F(x, u) := \begin{pmatrix} \nabla_x L(x, u) \\ g(x) \end{pmatrix} = 0.$$

In other words, the optimal solution and the corresponding multipliers are the solution of a system of $n + m$ nonlinear equations $F(x, u) = 0$ with $n + m$ unknowns $x \in \mathbb{R}^n$ and $u \in \mathbb{R}^m$.

Let (x_k, v_k) be an approximation of the solution. We apply Newton’s method and get an estimate for the next iterate by

$$\nabla F(x_k, v_k) \begin{pmatrix} d_k \\ y_k \end{pmatrix} + F(x_k, v_k) = 0.$$

After insertion, we obtain the equation

$$\begin{pmatrix} B_k & : & -\nabla g(x_k) \\ \nabla g(x_k)^T & : & 0 \end{pmatrix} \begin{pmatrix} d_k \\ y_k \end{pmatrix} + \begin{pmatrix} \nabla f(x_k) - \nabla g(x_k) v_k \\ g(x_k) \end{pmatrix} = 0 \quad (7)$$

with $B_k := \nabla_{xx} L(x_k, v_k)$. Defining now $u_k := y_k + v_k$, we get

$$B_k d_k - \nabla g(x_k) u_k + \nabla f(x_k) = 0$$

and

$$\nabla g(x_k)^T d_k + g(x_k) = 0.$$

But these equations are exactly the optimality conditions for the QP formulated for equality constraints only. To sum up, we get the following conclusion.

A SQP method is identical to Newton’s method for solving the KKT optimality conditions, if B_k is the Hessian of the Lagrangian

function and if we start sufficiently close to a solution.

Now, we assume again that we have inequality constraints instead of the equality ones. A straightforward analysis based on the optimality conditions shows that if $d_k = 0$ is an optimal solution of Equation (5) and u_k the corresponding multiplier vector, then x_k and u_k satisfy the necessary optimality conditions of Equation (1).

Note that the above analysis also serves to point out the crucial role of the dual variable u_k . To get a fast convergence rate as expected for Newton's method, we have to adapt the multiplier values accordingly together with the primal ones.

To avoid the computation of second derivatives, B_k is set to a positive definite approximation of the Hessian of the Lagrangian function. For the global convergence analysis, any choice of B_k is appropriate as long as the eigenvalues are bounded away from zero. However, to guarantee a superlinear convergence rate, we update B_k by a quasi-Newton method, for example, the BFGS formula

$$B_{k+1} := B_k + \frac{y_k y_k^T}{s_k^T y_k} - \frac{B_k s_k s_k^T B_k}{s_k^T B_k s_k} \quad (8)$$

with

$$\begin{aligned} y_k &:= \nabla_x L(x_{k+1}, u_k) - \nabla_x L(x_k, u_k), \\ s_k &:= x_{k+1} - x_k. \end{aligned} \quad (9)$$

Usually, we start with the unit matrix for B_0 and stabilize the formula by requiring that $a_k^T b_k \geq 0.2 b_k^T B_k b_k$. Positive definite matrices B_k guarantee unique solutions and in addition, a sufficient descent property of a merit function needed for the global convergence analysis.

Moreover, it is possible to proceed from a Cholesky factorization of B_k in the form

$$B_k = L_k L_k^T$$

with a lower triangular matrix L_k and to update L_k directly to get a factorization of B_{k+1} , see Gill *et al.* [15],

$$B_{k+1} = L_{k+1} L_{k+1}^T = L_k L_k^T + a_k a_k^T - b_k b_k^T.$$

A particular advantage is that an initial Cholesky decomposition is avoided, if a primal–dual method is applied to solve the QP (5).

Note that the above motivation proceeds from a local approximation of a solution. If starting from an arbitrary $x_0 \in \mathbb{R}^n$, $u_0 \in \mathbb{R}^m$, one has to stabilize the algorithm by introducing additional safeguards, for example, a line search, a trust region, or a filter. These three possibilities are discussed in the subsequent sections.

REDUCED HESSIAN SQP STEPS

The linear system (7) derived from the QP subproblem can be rewritten as

$$\begin{pmatrix} Y_k^T B_k Y_k & Y_k^T B_k Z_k & -R_k \\ Z_k^T B_k Y_k & Z_k^T B_k Z_k & 0 \\ -R_k^T & 0 & 0 \end{pmatrix} \times \begin{pmatrix} p_k \\ q_k \\ y_k \end{pmatrix} = \begin{pmatrix} -Y_k^T \nabla f(x_k) \\ -Z_k^T \nabla f(x_k) \\ g(x_k) \end{pmatrix}, \quad (10)$$

if we have the QR factorization

$$\nabla g(x_k) = (Y_k, Z_k) \begin{pmatrix} R_k \\ 0 \end{pmatrix},$$

and if we use the notation $p_k = Y_k^T d_k$ and $q_k = Z_k^T d_k$. Thus, it is easy to see that p_k and q_k can be obtained by

$$\begin{pmatrix} Z_k^T B_k Y_k & Z_k^T B_k Z_k \\ -R_k^T & 0 \end{pmatrix} \begin{pmatrix} p_k \\ q_k \end{pmatrix} = \begin{pmatrix} -Z_k^T \nabla f(x_k) \\ g(x_k) \end{pmatrix}, \quad (11)$$

which indicates that we only need the reduced matrix $Z_k^T B_k$ instead of the full matrix B_k to compute the QP step d_k . Hence, Nocedal and Overton [16] suggest to replace $Z_k^T B_k$ by a quasi-Newton matrix $\bar{B}_k$, and to obtain the QP step d_k by solving

$$\begin{pmatrix} \bar{B}_k \\ -\nabla g(x_k)^T \end{pmatrix} d = \begin{pmatrix} -Z_k^T \nabla f(x_k) \\ g(x_k) \end{pmatrix}. \quad (12)$$

The matrix $\bar{B}_k \in \mathbb{R}^{(n-m) \times n}$ is a quasi-Newton matrix that approximates $Z_k^T \nabla_{xx}^2 L(x_k, u_k)$,

which can be updated by the Broyden's unsymmetric Rank-1 formula

$$\bar{B}_{k+1} := \bar{B}_k + \frac{(\bar{y}_k - \bar{B}_k s_k) s_k^T}{\|s_k\|_2^2},$$

where $s_k := x_{k+1} - x_k$ and $\bar{y}_k := Z_{k+1}^T \nabla f(x_{k+1}) - Z_k^T \nabla f(x_k)$. This approach can be more efficient than the standard SQP because it reduces storage and calculation due to the fact that it uses a reduced matrix $B_k \in \mathbb{R}^{(n-m) \times n}$ instead of the full matrix B_k , particularly when m is close to n , namely, for problems there are lots of variables and constraints but less freedom in the variables. Moreover, this approach preserves the q-superlinearly convergent property of the standard SQP step, for example, see Nocedal and Overton [16].

We move along this direction further. If we replace $Z_k^T B_k Z_k$ by a quasi-Newton matrix $\hat{B}_k$ and replace $Z_k^T B_k Y_k$ by zero in the linear system (11), we obtain

$$\begin{pmatrix} 0 & \hat{B}_k \\ -R_k^T & 0 \end{pmatrix} \begin{pmatrix} p_k \\ q_k \end{pmatrix} = \begin{pmatrix} -Z_k^T \nabla f(x_k) \\ g(x_k) \end{pmatrix}. \quad (13)$$

The reason for doing so is that Powell [4] discovered that the SQP method converges two-step Q-superlinearly,

$$\lim_{k \rightarrow \infty} \frac{\|x_{k+1} - x^*\|}{\|x_{k-1} - x^*\|} = 0, \quad (14)$$

provided that $Y_k^T B_k Z_k$ is bounded. An advantage of this approach, which is called *two-side reduced Hessian method*, compared to Nocedal and Overton's one-side reduced Hessian method, is that the matrix $\hat{B}_k$ is a square matrix and can be kept positive definite by updates such as the BFGS formula. Furthermore, the computation cost is also reduced. But, the price we have to pay is that we can only prove two-step Q-superlinear convergence (14) instead of the one-step Q-superlinear convergence. Indeed, examples exist to show that the two-step Q-superlinear convergence of the two-side reduced Hessian method cannot be improved to one-step Q-superlinear convergence, for example, see Byrd [17] and Yuan [18].

STABILIZATION BY LINE SEARCH

We have seen in the previous sections that one should better approximate the actual primal and dual variables simultaneously to satisfy the optimality conditions of (1) based on the Newton method. Thus, we define $z_k := (x_k, v_k)$, where $x_k \in \mathbb{R}^n$ and $v_k \in \mathbb{R}^m$ are approximations of a KKT point in the k th step. A new iterate is then computed from

$$z_{k+1} := z_k + \alpha_k p_k, \quad (15)$$

where $p_k := (d_k, y_k) = (d_k, u_k - v_k)$ is the search direction obtained from solving the QP (5), see also Equation (7), and where α_k is a scalar parameter called the *step length*. The goal is to compute a sufficiently accurate step size within as few function evaluations as possible, so that the underlying algorithm converges. α_k should satisfy at least a sufficient decrease condition of a merit function

$$\phi_r(\alpha) := \psi_r \left(\begin{pmatrix} x \\ v \end{pmatrix} + \alpha \begin{pmatrix} d \\ u - v \end{pmatrix} \right) \quad (16)$$

with a suitable penalty function $\psi_r(x, v)$ and with $r = (r_1, \dots, r_m)^T \in \mathbb{R}^m$, a vector of m positive penalty parameters.

A merit function is supposed to contain information about the objective function to be minimized, and the violation of constraints. The first one studied in the context of SQP methods was the L_1 penalty function

$$\psi_r(x, v) := f(x) + \sum_{j=1}^m r_j g_j(x)^-, \quad (17)$$

where $g_j(x)^- := -\min(0, g_j(x))$ denotes violated constraints, see Han [3]. $\psi_r(x, v)$ is a so-called exact penalty function, that is, a minimizer of $\psi_r(x, v)$ subject to x for sufficiently large r is also a solution of NLP. But there are two severe drawbacks: $\psi_r(x, v)$ is nondifferentiable preventing efficient algorithms and, since $\psi_r(x, v)$ does not depend on multiplier information, it enables the Maratos effect [19], that is, the possibility of very slow convergence close to a solution.

Instead of Equation (17), augmented Lagrangian merit functions

$$\psi_r(x, v) := f(x) - v^T g(x) + \frac{1}{2} \sum_{j=1}^m r_j g_j(x)^2 \quad (18)$$

are an appropriate alternative, which differs by the choice of the multiplier approximation, see Boggs and Tolle [7] or Gill *et al.* [20]. A slightly different augmented Lagrangian function is given by

$$\begin{aligned} \psi_r(x, v) := & f(x) - \sum_{j \in J} (v_j g_j(x) \\ & - \frac{1}{2} r_j g_j(x)^2) - \frac{1}{2} \sum_{j \in K} v_j^2 / r_j \end{aligned} \quad (19)$$

with $J := \{j : 1 < j \leq m, g_j(x) \leq v_j / r_j\}$ and $K := \{1, \dots, m\} - J$, see Schittkowski [21] and Rockafellar [22], but very many other merit functions have been investigated in the past.

In all cases, the objective function is *penalized* as soon as an iterate leaves the feasible domain. The corresponding penalty parameters r_j , $j = 1, \dots, m$, which control the degree of constraint violation, must be carefully chosen to guarantee a descent direction of the merit function, see Schittkowski [21] or Wolfe [23] in a more general setting, that is, to achieve at least

$$\phi_{r_k}(0) = \nabla \psi_{r_k}(x_k, v_k)^T \begin{pmatrix} d_k \\ u_k - v_k \end{pmatrix} < 0 \quad (20)$$

when applied in the k -iteration step.

The implementation of a line search algorithm is a crucial issue when implementing a nonlinear programming algorithm, and has significant effect on the overall efficiency of the resulting code. On the one hand, we need a line search to stabilize the algorithm. On the other hand, it is not desirable to waste too many function calls. Moreover, the behavior of the merit function becomes irregular in case of constrained optimization because of very steep slopes at the border caused by large penalty terms. The implementation is more complex than shown above, if linear constraints and bounds of the variables are to be satisfied during the line search.

Usually, the step length parameter α_k is chosen to satisfy a certain Armijo [24] condition, that is, a sufficient descent condition

of a merit function, which guarantees convergence to a stationary point. However, to take the curvature of the merit function into account, we need some kind of compromise between a polynomial interpolation, typically a quadratic one, and a reduction of the step size by a given factor, until a stopping criterion is reached. Since $\phi_r(0)$, $\phi'_r(0)$, and $\phi_r(\alpha_i)$ are given, and α_i is the actual iterate of the line search procedure, we easily get the minimizer of the quadratic interpolation. We accept then the maximum of this value and the Armijo parameter as a new iterate, as shown by the subsequent code fragment.

Algorithm 1. Let β , μ with $0 < \beta < 1$, $0 < \mu < 0.5$ be given.

Start: $\alpha_0 = 1$

For $i = 0, 1, 2, \dots$ do:

1. If $\phi_r(\alpha_i) < \phi_r(0) + \mu \alpha_i \phi'_r(0)$, then stop.
2. Compute $\bar{\alpha}_i := \frac{0.5 \alpha_i^2 \phi'_r(0)}{\alpha_i \phi'_r(0) - \phi_r(\alpha_i) + \phi_r(0)}$.
3. Let $\alpha_{i+1} := \max(\beta \alpha_i, \bar{\alpha}_i)$.

The algorithm goes back to Powell [4] and corresponding convergence results are found in Schittkowski [21]. $\bar{\alpha}_i$ is the minimizer of the quadratic interpolation, and we use the Armijo descent property for checking termination. Step 3 is required to avoid irregular values, since the minimizer of the quadratic interpolation could be outside of the feasible domain $(0, 1]$. Additional safeguards are required, for example, to prevent violation of bounds. Algorithm 1 assumes that $\phi_r(1)$ is known before calling the procedure, that is, that the corresponding function values are given. We stop the algorithm if sufficient descent is not observed after a certain number of iterations. If the tested step size falls below machine precision or the accuracy by which model function values are computed, the merit function cannot decrease further.

It is possible that $\phi'_r(0)$ becomes negative due to round-off errors in the partial derivatives or that Algorithm 1 breaks down because of too many iterations. In this case, we proceed from a descent direction of the merit function, but $\phi'_r(0)$ is extremely small. To avoid interruption of the whole iteration process, the idea is to repeat the line search

with another stopping criterion. Instead of testing Equation (20), we accept a step size α_k as soon as the inequality

$$\phi_{r_k}(\alpha_k) \leq \max_{k-p(k) \leq j \leq k} \phi_{r_j}(0) + \alpha_k \mu \phi'_{r_k}(0) \quad (21)$$

is satisfied, where $p(k)$ is a nondecreasing integer with $p(k) := \min\{k, p\}$, p a given tolerance. Thus, we allow an increase of the reference value $\phi_{r_{j_k}}(0)$ in a certain error situation, that is, an increase of the merit function value.

To implement the nonmonotone line search, we need a queue consisting of merit function values at previous iterates. In case of $k = 0$, the reference value is adapted by a factor greater than 1, that is, $\phi_{r_{j_k}}(0)$ is replaced by $t\phi_{r_{j_k}}(0)$, $t > 1$. The basic idea to store reference function values and to replace the sufficient descent property by a sufficient “ascent” property in max-form, is described in Dai [25] and Dai and Schittkowski [26], where convergence proofs are presented. The general idea goes back to Grippo *et al.* [27], and was extended to constrained optimization and trust-region methods in a series of subsequent articles, see, for example, Toint [28,29].

STABILIZATION BY TRUST REGIONS

Another globalization technique for nonlinear optimization is trust region, where the next iterate requires to be in the neighborhood of the current point, namely, $\|x_{k+1} - x_k\| \leq \Delta_k$, where $\Delta_k > 0$ is the trust-region radius updated from iteration to iteration. Thus, an essential constraint of a trust-region subproblem is

$$\|d\|_2 \leq \Delta_k. \quad (22)$$

But, simply adding the trust-region constraint (22) to the QP (5) may lead to an infeasible subproblem. There are mainly three approaches in constructing trust region subproblems. To simplify our discussions, first we consider only equality constraints.

The first approach is the null-space technique, which was studied by many authors, including Vardi [30], Byrd *et al.* [31], and

Omojokun [32]. In this approach, the trial step s_k consists of a range-space step v_k and the null-space step h_k . v_k reduces the linearized constraint $\|\nabla g(x_k)^T d + g(x_k)\|$ and h_k reduces the approximate Lagrange function in the null space of $\nabla g(x_k)^T$. For example, v_k can be the least norm solution of

$$\begin{aligned} & \text{minimize } \|\nabla g(x_k)^T v + g(x_k)\|_2^2 \quad (23) \\ & v \in \mathbb{R}^n : \|v\|_2 \leq \delta \Delta_k, \end{aligned}$$

where $\delta \in (0, 1)$ is a given constant. The parameter $\delta < 1$ leaves freedom for defining h_k . Once v_k is computed, h_k can be obtained by solving

$$\begin{aligned} & \text{minimize } \frac{1}{2} (v_k + h)^T B_k (v_k + h) + \nabla f(x_k)^T h \\ & h \in \mathbb{R}^n : \nabla g(x_k)^T h = 0 \quad (24) \\ & \|h\|_2 \leq \sqrt{1 - \delta^2} \Delta_k. \end{aligned}$$

The trust-region step $s_k := v_k + h_k$ obtained by the null space technique can be regarded as the solution of the QP

$$\begin{aligned} & \text{minimize } \frac{1}{2} d^T B_k d + \nabla f(x_k)^T d \\ & d \in \mathbb{R}^n : \nabla g(x_k)^T d + \theta_k g(x_k) = 0 \quad (25) \\ & \|d\|_2 \leq \Delta_k \end{aligned}$$

for some parameter $\theta_k \in (0, 1]$.

The second approach is to replace all the linearized constraints in Equation (5) by a single quadratic constraint, which was proposed by Celis *et al.* [33],

$$\begin{aligned} & \text{minimize } \frac{1}{2} d^T B_k d + \nabla f(x_k)^T d \\ & d \in \mathbb{R}^n : \|\nabla g(x_k)^T d + g(x_k)\|_2 \leq \xi_k \quad (26) \\ & \|d\|_2 \leq \Delta_k, \end{aligned}$$

where $\xi_k \geq \min_{\|d\|_2 \leq \Delta_k} \|\nabla g(x_k)^T d + g(x_k)\|_2$ to ensure the subproblem is feasible. One particular choice for ξ_k is given by Powell and Yuan [34]:

$$\begin{aligned} & \min_{\|d\|_2 \leq \delta_1 \Delta_k} \|\nabla g(x_k)^T d + g(x_k)\|_2 \leq \xi_k \\ & \leq \min_{\|d\|_2 \leq \delta_2 \Delta_k} \|\nabla g(x_k)^T d + g(x_k)\|_2 \end{aligned}$$

where $0 < \delta_2 < \delta_1 < 1$ are two constants.

The third type of trust-region subproblems is to minimize an approximation of some penalty function. On the basis of the L_∞ exact penalty, Yuan [35] suggests

$$\begin{aligned} \text{minimize } \Phi_k(d) &:= \frac{1}{2} d^T B_k d + \nabla f(x_k)^T d \\ &+ \sigma_k \|\nabla g(x_k)^T d + g(x_k)\|_\infty \quad (27) \\ d \in \mathbb{R}^n : &\|d\|_\infty \leq \Delta_k, \end{aligned}$$

which can be converted into a standard QP. The penalty parameter $\sigma_k > 0$ may need to be updated to ensure the sufficient reduction in the norm of the residuals of linearized constraints. The L_∞ penalty function in Equation (27) can be replaced by any other penalty functions, including the augmented Lagrange function studied by Niu and Yuan [36]. For example, if we use the L_1 penalty function, it leads to the famous SL_1 QP method given by Fletcher [37].

Once the trial step s_k is computed, a trust-region algorithm for constrained optimization can be given as follows.

Algorithm 2. (A general trust-region SQP method)

Let $0 < \tau_3 < \tau_4 < 1 < \tau_1$, $0 < \tau_2 < 1$, and $x_0 \in \mathbb{R}^n$ be given.

For $k = 0, 1, 2, \dots$ until convergence do

1. Compute the trial step s_k .
2. Compute the ratio between actual reduction and predicted reduction in a merit function Ψ_k ,

$$r_k := \frac{\Psi_k(x_k) - \Psi_k(x_k + s_k)}{Pred_k}$$

3. Let

$$x_{k+1} := \begin{cases} x_k + s_k & \text{if } r_k > 0, \\ x_k & \text{otherwise,} \end{cases}$$

and

$$\Delta_{k+1} \in \begin{cases} [\tau_3 \|s_k\|_2, \tau_4 \Delta_k] & \text{if } r_k < \tau_2, \\ [\Delta_k, \tau_1 \Delta_k] & \text{otherwise.} \end{cases}$$

4. Update B_{k+1} and define $\Psi_{k+1}(x)$.

For different trust-region algorithms, $Pred_k$ and $\Psi_k(x)$ have to be chosen accordingly. For the L_∞ trust-region algorithm of Yuan [35], we have that

$$\Psi_k(x) := f(x) + \sigma_k \|g(x)\|_\infty$$

and

$$Pred_k := \Phi_k(0) - \Phi_k(s_k),$$

where $\Phi_k(d)$ is defined in Equation (27). The general requirements for $Pred_k$ are that it is always positive and it is a good approximation to the actual reduction in the merit function, particularly near the solution.

Unless the merit function $\Psi_k(x)$ is a differentiable penalty function, Maratos-effect will occur. Thus, it is necessary to try a second-order correction step $\hat{s}_k$ whenever the standard trust region trial step s_k is not acceptable. Normally, the second order correction step $\hat{s}_k$ is computed by solving another subproblem, which is a slight modification of the trust subproblem for obtaining s_k . For example, if s_k is obtained by Equation (27), we can compute $\hat{s}_k$ by solving the following Second-order correction subproblem,

$$\begin{aligned} \text{minimize } &\frac{1}{2} (s_k + d)^T B_k (s_k + d) + \nabla f(x_k)^T d \\ &+ \sigma_k \|\nabla g(x_k)^T d + g(x_k + s_k)\|_\infty \quad (28) \\ d \in \mathbb{R}^n : &\|s_k + d\|_\infty \leq \Delta_k. \end{aligned}$$

As the new subproblem differs from the original subproblem only by a term $g(x_k + s_k) - g(x_k) - \nabla g(x_k)^T s_k$ which is of magnitude of $\|s_k\|^2$, one can easily show that $\|\hat{s}_k\| = O(\|s_k\|^2)$, hence adding $\hat{s}_k$ will retain the nice superlinearly convergent property of the SQP step s_k . More important is that the second-order correction step $\hat{s}_k$ will always make the merit function accept the new point $x_k + s_k + \hat{s}_k$ when x_k is close to the solution, which was first proved by Yuan [38].

Now, we give a brief discussion about inequality constraints. The inequality constraints in Equation (1) can be transformed into equality constraints

$$g(x) - s = 0$$

by introducing slack variables $s = (s_1, \dots, s_m)^T \in \mathbb{R}^m$, with the additional nonnegative constraints:

$$s \geq 0. \quad (29)$$

The nonnegative constraints (29) can be handled by the log-barrier function or by scaled trust-region techniques, for example, see Dennis *et al.* [39], Coleman and Li [40], and Byrd *et al.* [41].

For detailed discussions about trust-region SQP methods, we recommend the related chapters in the monograph by Conn, Gould and Toint [42] and the review article of Yuan [43].

STABILIZATION BY A FILTER

Filter method was first given by Fletcher and Leyffer [44]. This approach is based on viewing the constrained optimization problem (1) as two separate minimization problems,

$$\begin{aligned} &\text{minimize } f(x) \\ &x \in \mathbb{R}^n \end{aligned}$$

and

$$\begin{aligned} &\text{minimize } h(g(x)) \\ &x \in \mathbb{R}^n, \end{aligned}$$

where

$$h(g(x)) := \|g^-(x)\|_1 = \sum_{j=1}^m |\min(0, g_j(x))|.$$

For each iterate point x_k , there is a corresponding pair

$$(f_k, h_k) = (f(x_k), \|g^-(x_k)\|_1),$$

see the subsequent sketch.

The concept of domination is crucial for the filter method.

Definition 1. A pair (f_k, h_k) is said to dominate another pair (f_l, h_l) if and only if both $f_k < f_l$ and $h_k < h_l$.

The idea of the filter approach is that a new point is acceptable as long as it is not dominated by any previous iterates. Such an acceptable point will be added to the filter which is used to control subsequent iterates.

Definition 2. A filter is a list of pairs (f_l, h_l) such that no pair dominates any other. A point (f_k, h_k) is said to be acceptable for inclusion in the filter if it is not dominated by any point in the filter.

At each iteration, a Filter-SQP algorithm needs to construct a QP subproblem. Fletcher and Leyffer [44] uses the subproblem

$$\begin{aligned} &\text{minimize } \frac{1}{2} d^T B_k d + \nabla f(x_k)^T d \\ &d \in \mathbb{R}^n : \nabla g(x_k)^T d + g(x_k) \geq 0 \quad (30) \\ &\|d\|_\infty \leq \Delta_k. \end{aligned}$$

The outlines of a general filter-SQP algorithm can be stated as follows.

Algorithm 3. (A general filter-SQP algorithm)

Given $x_0 \in \mathbb{R}^n$, let $k := 1$. Let the initial filter be the pair $\{(f_0, h_0)\}$.

For $k = 0, 1, 2, \dots$ until convergence do

1. Solve the QP subproblem obtaining d_k .
2. Provisionally set $x_{k+1} := x_k + d_k$.
3. If (f_{k+1}, h_{k+1}) is dominated by some pair in the filter then $x_{k+1} := x_k$. Otherwise, accept x_{k+1} , add (f_{k+1}, h_{k+1}) to the filter and remove all points dominated by (f_{k+1}, h_{k+1}) from the filter.
4. Construct the QP subproblem for the next iteration.

It is well known that when using a penalty function to ensure global convergence of nonlinear optimization algorithms, we normally require some sufficient decrease in the penalty function. Similarly, in the implementation of a filter method, the simple domination has to be replaced by some sufficient domination. Fletcher and Leyffer

[44] suggest to accept the provisional point x_{k+1} to the filter if either

$$h_{k+1} \leq 0.99h_l$$

or

$$f_{k+1} \leq f_k - \max(0.25\Delta q_l, 10^{-4}h_l\mu_l)$$

holds for all filter entries l , where $\Delta q_l := -\frac{1}{2}d_l^T B_l d_l - \nabla f(x_l)^T d_l$ is the predicted reduction of $f(x)$ based on the quadratic model, λ_l is the Lagrange multiplier of Equation (30), and μ_l is the projection of the least power of 10 larger than $\|\lambda_l\|_\infty$ in the interval $[10^{-6}, 10^6]$.

The trust-region QP subproblem (30) may become infeasible, either because the trust-region radius Δ_k is too small or due to the inconsistency of the linearized constraints. Thus, a restoration phase has to be used to move the iterate toward the feasible region. This is achieved by minimizing the norm of the residuals of the linearized constraints in the trust region.

CONVERGENCE

There remains the question whether the convergence of an SQP method can be proved in a mathematically rigorous way. In fact there exist numerous theoretical convergence results in the literature; see for example, Boggs and Tolle [7]. We give here only an impression about the type of these statements, and repeat some results that have been stated in the early days of the SQP methods.

In the first case, we consider the global convergence behavior, that is, the question, whether the SQP methods converges when starting from an arbitrary initial point. Suppose that the augmented Lagrangian merit function (18) is implemented and that the primal and dual variables are updated in the form (15).

Theorem 1. *Let $\{(x_k, v_k)\}$ be a bounded iteration sequence of the SQP algorithm with a bounded sequence of quasi-Newton matrices $\{B_k\}$ and assume that*

$$d_k^T B_k d_k \geq \gamma d_k^T d_k \quad (31)$$

for all k and a $\gamma > 0$. Then there is an accumulation point of $\{(x_k, v_k)\}$ satisfying the KKT conditions for (1).

The statement of the theorem is quite weak. But without any further information about second derivatives, we cannot guarantee that the approximated point is indeed a local minimizer.

To investigate now the local convergence speed, we start from an initial $x_0 \in \mathbb{R}^n$ that is sufficiently close to an optimal solution. Normally, we find the following assumptions for local convergence analysis.

Assumption 1. Assume that

1. $x_k \rightarrow x^*$,
2. $f(x), g_1(x), \dots, g_m(x)$ are at least twice continuously differentiable,
3. $g_i(x^*) = 0$ for $i = 1, \dots, m$, that is, we know all active constraints,
4. $\nabla g_i(x^*)$ are linearly independent for $i = 1, \dots, m$, that is, the constraint qualification is satisfied,
5. x^* is a KKT point and u^* is the corresponding Lagrange multiplier,
6. The inequality

$$d^T \nabla_{xx}^2 L(x^*, u^*) d > 0$$

holds for all non-zero vectors d satisfying $\nabla g(x^*)^T d = 0$, that is, a second-order sufficient condition is satisfied.

The following theorem is the fundamental result for local convergence analysis of SQP methods.

Theorem 2. *Assume that the conditions in Assumption 1 are satisfied. Let d_k be the solution of*

$$\text{minimize } \frac{1}{2} d^T B_k d + \nabla f(x_k)^T d \quad (32)$$

$$d \in \mathbb{R}^n : \nabla g(x_k)^T d + g(x_k) = 0.$$

Then, the limit

$$\lim_{k \rightarrow \infty} \frac{\|x_k + d_k - x^*\|}{\|x_k - x^*\|} = 0 \quad (33)$$

holds if and only if

$$\lim_{k \rightarrow \infty} \frac{\|P_k(B_k - \nabla_{xx}^2 L(x^*, u^*)d_k)\|}{\|d_k\|} = 0 \quad (34)$$

where P_k is the projection from $\mathbb{R}^n$ onto the null space of $\nabla g(x_k)^\top$, and $\nabla_{xx}^2 L(x^*, u^*)$ is the Hessian of the Lagrangian at the solution x^* .

This important result was first given by Boggs *et al.* [45] and Powell [46]. A nice proof for this result can be found in Stoer and Tapia [47].

In order to apply Theorem 2 to establish suplinear convergence results for various SQP methods, the general approach is to prove that $x_{k+1} = x_k + d_k$ holds eventually, where d_k is the solution for the QP subproblem (32). Thus, for line search SQP methods we need to prove that the unit step length $\alpha_k = 1$ can be accepted by the corresponding line search conditions. While for trust-region SQP algorithms, one has to show that the trust-region constraint $\|d\| \leq \Delta_k$ will be inactive and the d_k can be accepted by the algorithm for all large k . And, for filter-SQP algorithms, it is required to show that $x_k + d_k$ will be accepted by the filter for all large k .

However, no matter what line search or trust region is used for globalization of the SQP method, due to the Maratos effect, $x_k + d_k$ may not be accepted though Equation (33) is true, when the merit function is a nonsmooth exact penalty function. Even for filter methods, Maratos effect can also happen because a superlinearly convergent SQP step d_k can sometimes increase both the objective function f and the constraint violations $h(g)$. To overcome the Maratos effect, there are many techniques, which can be grouped into four categories. The first one is the watchdog technique, in which standard line search conditions are relaxed at some iterations. The watchdog technique was proposed by Chamberlain *et al.* [48]. The second is the second-order correction technique, where an additional subproblem is solved to obtain an accepted full step, for example, see Fletcher [49], Mayne and Polak [50], and Fukushima [51]. The third is to use a smooth exact penalty function or the augmented Lagrange function as the merit

function; for example, see Schittkowski [21], Powell and Yuan [34,52], and Ulbrich [53]. The fourth is the nonmonotone technique, for example, see Ulbrich and Ulbrich [54], and Gould and Toint [55].

From the characterization of the local convergence property of the SQP method given in Theorem 2, the superlinear convergence of a specific SQP method depends on the relation Equation (34), which is generally hard to verify directly if B_k is updated by quasi-Newton updates. The standard approach is more or less following the sophisticated and elegant technique for analyzing quasi-Newton methods for unconstrained optimization given by Dennis and Moré [56,57]. Their technique is to prove the local Q-superlinear convergence by two steps. The first step is to show that the sequence $\{x_k\}$ converges R-linearly. Then, the R-linear convergence of the sequence is used to obtain more local convergence properties, such as the following relations

$$\sum_{k=1}^{\infty} \|x_{k+1} - x_k\| < \infty, \quad \sum_{k=1}^{\infty} \|x_k - x^*\| < \infty,$$

the uniform boundedness of B_k and B_k^{-1} , and the limit (34), in order to establish the Q-superlinear convergence of the sequence $\{x_k\}$.

However, for a given specific quasi-Newton method, there is still a gap to apply the beautiful convergence results discussed above. For example, it is not easy to know whether condition (31) holds for a particular quasi-Newton updates. Moreover, to ensure the update formulae generate positive definite matrices, we always require $s_k^\top y_k > 0$, a condition that is normally satisfied for unconstrained optimization. However, for constrained optimization problems, as the solution (x^*, u^*) is only a saddle point of the Lagrange function, the vector y_k defined by Equation (9) cannot guarantee $s_k^\top y_k > 0$. Powell [5] suggests replacing y_k by the vector

$$\bar{y}_k = \begin{cases} y_k, & \text{if } s_k^\top y_k > 0.2s_k^\top B_k s_k \\ t_k y_k + (1 - t_k)B_k s_k, & \text{otherwise,} \end{cases} \quad (35)$$

where $t_k = 0.8s_k^\top B_k s_k / (s_k^\top B_k s_k - s_k^\top y_k)$. With this modification, Powell [5] proved the

following remarkable result for the SQP method with BFGS update.

Theorem 3. *Assume that the above assumptions are valid and $\alpha_k = 1$ for all k . Then the sequence $\{x_k\}$ converges R -superlinearly, that is,*

$$\lim_{k \rightarrow \infty} \|x_{k+1} - x^*\|^{1/k} = 0.$$

The R -superlinear convergence speed of $\{x_k\}$ is somewhat weaker than the Q -superlinear convergence rate of $\{z_k := (x_k, v_k)\}$ defined below which was first proved in the form

$$\lim_{k \rightarrow \infty} \frac{\|z_{k+1} - z^*\|}{\|z_k - z^*\|} = 0$$

for the so-called DFP update formula, that is, a slightly different quasi-Newton method. In this case, we get a sequence β_k tending to zero with

$$\|z_{k+1} - z^*\| \leq \beta_k \|z_k - z^*\|.$$

But, it should be noted that the Q -superlinear convergence of z_k does not imply the Q -superlinear convergence of x_k .

SERIES SYSTEMS

INTRODUCTION

There are many ways in which a system can be configured to function properly. It could be as simple as a series system, parallel system, or as complex in structure as a network. Once the system is configured in a proper manner, then it is evaluated to test the reliability to meet the performance criteria and the acceptable reliability level. In this article, we study the series system and evaluate its reliability.

In a traditional gasoline car, for the engine to work, we need several different parts to operate in sequence. In detail, a piston in the engine starts from the top and is pushed down to intake the mixture of air and gasoline into a cylinder. Then the piston is pushed back up to compress the mixture. When the piston is at the top, the spark plug functions to ignite the gasoline, causing it to explode in the cylinder; it then pushes the piston back down. When the piston is back at the bottom, the valve opens and lets the air and gas out. As can be seen from the above process, if any of the parts fail to operate, we are not able to start the engine and hence the car does not move. Similar real life examples can be found in systems such as refrigerator, flash lights, computer, and so on. In general, a series system functions successfully only when all the components function properly. This indicates that every component should work successfully in order for the system to work. Consider a series system consisting of q components as shown in Fig. 1.

The above shows that a system with q components is connected in series such that, if any of the component fails to function, this

will result in the failure of function of the next component. Therefore, for a series system to succeed, all of its components must function well during the intended mission time of the system.

Since all components of the entire system should successfully operate in a series system, the reliability of this series system is the probability that all components succeed. This implies that all q components in the system must succeed. Let R_s be the reliability of the system, Z_i be the indicator where the i th component functions (does not fail), and $P(Z_i)$ be the probability that the i th component is operational. The reliability of the system is then expressed as

$$\begin{aligned} R_s &= P(Z_1 \cap Z_2 \cap \dots \cap Z_q) \\ &= P(Z_1) \cdot P(Z_2|Z_1) \cdot P(Z_3|Z_1 \cdot Z_2) \cdots \\ &\quad P(Z_q|Z_1 \cdot Z_2 \cdots Z_{q-1}). \end{aligned} \quad (1)$$

Since the above equation is expressed as a conditional probability, this also includes the case in which the previous failure impacts the following failure rates. However, if each component's failure rate is independent, then the equation can be written as

$$\begin{aligned} R_s &= P(Z_1) \cdot P(Z_2) \cdot P(Z_3) \cdots P(Z_q) \\ &= \prod_{i=1}^q P(Z_i). \end{aligned} \quad (2)$$

Additionally, for a simple series system, the reliability of the system can be calculated from the reliability of its individual components [1].

$$R_s = \prod_{i=1}^q R_i. \quad (3)$$

We are going to develop the warranty cost model for the series system. First, we briefly review the warranty policy. In general, warranty is an obligation attached to products that require the manufacturers to provide compensation for consumers according to the

Figure 1. Series system with q components.

warranty terms when the warranted products fail to perform their intended functions [2]. The warranty is nowadays important not only to the manufacturers but also to the buyers of any commercial product. The consumer is provided a resource for dealing with items that fail due to the uncertainty of product performance. The manufacturer is provided protection because warranty terms explicitly limit responsibility in terms of both time and type of product failure.

To develop the cost model for the series system, several assumptions have been made in this article as follows: (i) The repair cost and the replacement cost are constant. (ii) Repair service time and replacement service time are negligible. (iii) All warranty claims are executed and all claims are valid. (iv) Repairs are imperfect and the repair process can be modeled by a quasi-renewal process (QRP). (v) The time to perform an inspection in which to determine whether the failed component needs repair or a replacement is negligible. (vi) The warranty period is renewable. (vii) Each component's failure rate is independent in the series system.

BACKGROUND

Many researchers [3–5] have studied the optimization of system reliability using different techniques and have investigated various characteristics and reliability of the series system. Duarte *et al.* [3] developed the method to solve the problem of maintenance management of a series system based on preventive maintenance over the different system components. Nahas and Nourelfath [4] studied a reliability optimization problem for a series system to maximize the system reliability subject to the system budget. Xu *et al.* [5] proposed a computational approach for the reliability redundancy optimization problem. Warranty models and their properties have been investigated by many researchers [6–8]. In Blischke and Murthy's books [6,7], general descriptions of various

kinds of warranty policies and mathematical models can be found. Park and Pham [8] developed the warranty cost models, reliability, and other measures for k -out-of- n systems using mixed and an altered QRPs.

To analyze the combination of the series system to the warranty, we use two concepts from the classic QRP, which are the altered QRP and the mixed QRP. The classic QRP model shows that the time to failure is reduced to a fraction α of the previous repair interval and this means that it is dependent of all repair intervals from the prior period. However, it is not easy to find such examples in real life. Therefore, to overcome this unpractical preposition, we develop an altered QRP with different parameters for interfailure intervals. Another alternate QRP is the mixed QRP. This allows an immediate replacement for a malfunctioning product within a warranty period in the case of a premature and severe malfunction despite the number of failures being less than a threshold level. On the basis of the two above-mentioned concepts, cost analysis for a series system is conducted.

In case the warranty policy is renewable, the distribution function of the number of failures can be obtained. If a product fails to perform within the warranty period w , the warranty policy is renewable for the same period w .

ALTERED QUASI-RENEWAL PROCESSES

Because the repair is assumed to be imperfect, the repair process can be modeled by a QRP. We first define QRP. On the basis of Wang and Pham's QRP [9], we present two alternate QRPs: the altered QRP and mixed QRP. The altered QRP is changing a parameter in the equations, and the mixed QRP is mixing repair intervals and replacement intervals. Then we investigate the distribution of the number of failures and develop the cost model for a single-component system in terms of the expected warranty cost and

the variance of the warranty cost. Finally, we develop the cost model for the series system.

Definition [9]. Let X_n be the interfailure interval between the $(n-1)$ th and n th events of the process. The counting process $\{N(t), t > 0\}$ is a *QRP* associated with the distribution F and the constant parameter α , $\alpha > 0$, if $X_n = \alpha^{n-1} \cdot Z_n$, $n = 1, 2, \dots$ where Z_n s are i.i.d. and $Z_n \sim F$.

The probability density function (pdf), cumulative distribution function (cdf), and failure rate, respectively, for $n = 2, 3, 4, \dots$ are given by

$$\begin{aligned} f_n(x) &= \frac{1}{\alpha^{n-1}} f_1\left(\frac{1}{\alpha^{n-1}}x\right) \\ F_n(x) &= F_1\left(\frac{1}{\alpha^{n-1}}x\right) \\ h_n(x) &= \frac{1}{\alpha^{n-1}} h_1\left(\frac{1}{\alpha^{n-1}}x\right). \end{aligned} \quad (4)$$

Altered Quasi-Renewal Process

From the classic QRP, each interoccurrence interval has a common pattern like $X_2 = \alpha \cdot X_1$, $X_3 = \alpha^2 \cdot X_1$, $X_4 = \alpha^3 \cdot X_1, \dots, X_n = \alpha^{n-1} \cdot X_1$. Let X_1 represent the first failure interval. This means that the failure time will be reduced with a fraction α . In reality, such a specific pattern would be difficult to observe. We now discuss an altered QRP that does not need to assume such a pattern.

Definition [8]. A counting process $\{N(t), t > 0\}$ is said to be the altered QRP associated with the distribution F and the random parameter $\beta_n, \beta_n > 0$, a constant, if $X_n = \beta_n \cdot X_1, n = 2, 3, \dots$ where $X_1 \sim F$ and β_n , where $n = 2, 3, \dots$ are not necessarily equal.

Let f_i and F_i be the pdf and cdf of X_i . For the altered QRP, the cdf and pdf for $n = 2, 3, 4, \dots$ are, respectively, given by

$$\begin{aligned} F_n(x) &= F_1\left(\frac{1}{\beta_n}x\right) \\ f_n(x) &= \frac{1}{\beta_n} f_1\left(\frac{1}{\beta_n}x\right). \end{aligned} \quad (5)$$

Additionally, the component j 's cdfs and pdfs of interoccurrence interval i , respectively, for $i = 2, 3, 4, \dots$ are given by

$$\begin{aligned} F_{ij}(x) &= F_{1j}\left(\frac{1}{\beta_{ij}}x\right) \\ f_{ij}(x) &= \frac{1}{\beta_{ij}} f_{1j}\left(\frac{1}{\beta_{ij}}x\right). \end{aligned} \quad (6)$$

Mixed Quasi-Renewal Processes

Bai and Pham [10] proposed a warranty model addressing the relationships between the number of repairs and replacements. Let h be an upper limit of the number of repairs under the warranty. Let N_a and N_b be the number of repair and replacement within a warranty period respectively. Similarly, let $N_a(t)$ and $N_b(t)$ be the number of repairs and the number of replacements at random variable time T respectively. w denotes a warranty period assuming that N_a and N_b are correlated and $\text{cov}(N_a, N_b) \neq 0$, then

$$\begin{aligned} N_a(w) < h &\rightarrow N_b(w) = 0, \\ N_b(w) > 0 &\rightarrow N_a(w) = h. \end{aligned} \quad (7)$$

This implies that, if there are less than h failures, the replacements would not occur, instead, only repair services would be provided. If there are h failures, a replacement would occur. In other words, if there are more than h system failures within w , the failed product will be replaced instead of being repaired again. The *repair-limit risk-free* warranty policies of a fixed period w , where a replacement only happens after h failures under a warranty period, are suggested [10]. However, in this article, we consider that the replacement would happen if the system failure is premature and severe because the likelihood of it occurring in real life is higher. Therefore, Equation (7) was altered to Equation (8) for the mixed QRP as follows:

$$\begin{aligned} N_a(w) < h &\rightarrow N_b(w) \geq 0, \\ N_b(w) > 0 &\rightarrow N_a(w) \leq h. \end{aligned} \quad (8)$$

In this model, even if there are less than h failures, the replacement strategies can

happen using mixed QRP. In the case of a failure of function of a product, either repair or replacement may be provided on the basis of the failure condition, and the manufacturer should select which services would be provided. Additionally, in general, the superposition of any two renewal processes is not a renewal process. Since we assume that the repairs and replacements would not happen simultaneously, they could be the renewal processes.

COST ANALYSIS

In this section, warranty cost analyses are elaborated through computation of both the expected value and the variance of the warranty cost. Also, the distribution of N and its properties per period and several statistical properties of warranty cost function per cycle or per product sold are shown.

Distribution of $N_s(t)$

Let $N_s(t)$ be the number of system failures at random variable time T within a warranty period w . Let $f_s(\cdot)$, $F_s(\cdot)$, and $R_s(\cdot)$ be the pdf, cdf, and reliability function respectively of system failure times within a warranty period w . We assume that the warranty policy is renewable after each repair/replacement. This section derives the distribution of the number of system failures within the warranty period. Under the perfect repair assumption, we can obtain the probability mass function (pmf) of N_s as follows [11]:

$$P[N_s = n_s] = [F_s(w)]^{n_s} R_s(w), \quad \text{for } n_s = 1, 2, 3, \dots \quad (9)$$

Lemma 1 [8]. *Let $f_{is}(\cdot)$, $F_{is}(\cdot)$, and $R_{is}(\cdot)$ be the pdf, cdf, and reliability function respectively of system failure times after $(i-1)$ th repair/replacement within a warranty period w . Under the imperfect repair, every $F_{is}(w)$ is different, so the pmf of N_s is given by*

$$P[N_s = n_s] = \left(\prod_{i=1}^{n_s} F_{is}(w) \right) \left(R_{(n_s+1)s}(w) \right). \quad (10)$$

We now discuss the cost analyses for a single-component system considering the interfailure intervals approach. From Ref. 8, the reliability function of a single-component system, which has n number of failures in the warranty period w , is given by

$$R_s(w) = \prod_{i=1}^n (R_{is}(w)) = \left(1 - \int f_{1s}(x) dx \right) \times \prod_{i=2}^n \left(1 - \int \frac{1}{\beta_{is}} f_{is} \left(\frac{1}{\beta_{is}} x \right) dx \right). \quad (11)$$

Using Equations (10) and (11), the pdf of the system failure times, $f(n)$, under the warranty is given by

$$\begin{aligned} f(n) &= \left(\prod_{i=1}^n F_{is}(w) \right) \left(R_{(n+1)s}(w) \right) \\ &= \left(\int f_{1s}(x) dx \right) \left(\prod_{i=2}^n \left(\int \frac{1}{\beta_{is}} f_{is} \left(\frac{1}{\beta_{is}} x \right) dx \right) \right) \\ &\quad \times \left(1 - \int \frac{1}{\beta_{(n+1)s}} f_{1s} \left(\frac{1}{\beta_{(n+1)s}} x \right) dx \right). \end{aligned} \quad (12)$$

The expected number of warranty repair services can be obtained as follows:

$$\begin{aligned} E(N_a) &= \int n_a \cdot f(n_a) \cdot dn_a = \int n_a \cdot \left(\int f_{1s}(x) dx \right) \\ &\quad \times \prod_{i=2}^{n_a} \left(\int \frac{1}{\beta_{is}} f_{is} \left(\frac{1}{\beta_{is}} x \right) dx \right) \\ &\quad \times \left(1 - \int \frac{1}{\beta_{(n+1)s}} f_{1s} \left(\frac{1}{\beta_{(n+1)s}} x \right) dx \right) \cdot dn_a. \end{aligned} \quad (13)$$

Therefore, the variance of the number of repaired services can be obtained by

$$\text{Var}(N_a) = E(N_a^2) - [E(N_a)]^2, \quad (14)$$

where $E(N_a^2) = \int n_a^2 \cdot f(n_a) \cdot dn_a$, and $f(n_a)$ is given in Equation (12) and $E(N_a)$ is given in Equation (13).

Similar to Equation (13), we obtain the expected number of replacement warranty services

$$E(N_b) = \int n_b \cdot \left(\prod_{i=1}^{n_b} \left(\int f_{is}(y) dy \right) \right) \left(1 - \int f_{is}(y) dy \right) \cdot dn_b. \quad (15)$$

The variance of the number of replacement services could be obtained.

Let c_a and c_b be the repair cost per failure and replacement cost per failure respectively. For the warranty cost per product sold, C , the expected warranty cost is given by

$$E(C) = c_a E(N_a) + c_b E(N_b), \quad (16)$$

where $E(N_a)$ is given in Equation (13) and $E(N_b)$ is given in Equation (15).

Note that

$$\begin{aligned} E[N_a N_b] &= \sum_{n_b=0}^{\infty} \sum_{n_a=0}^h n_a n_b P[N_a = n_a, N_b = n_b] \\ &= \sum_{n_b=0}^{\infty} \sum_{n_a=0}^h n_a n_b P[N_s = n_s] \\ &= \sum_{n_b=0}^{\infty} \sum_{n_a=0}^h n_a n_b \left(\prod_{i=1}^{n_a+n_b} (F_{is}(w)) \right) \\ &\quad \times (R_{(n_a+n_b+1)s}(w)). \end{aligned} \quad (17)$$

The covariance of the number of repair services and the replacement services can be obtained as follows:

$$\text{Cov}(N_a, N_b) = E[N_a N_b] - E[N_a]E[N_b], \quad (18)$$

where $E[N_a]$, $E[N_b]$, and $E[N_a N_b]$ are given in Equations (13), (15), and (17).

The variance of the warranty system cost is given by

$$\begin{aligned} \text{Var}(C) &= c_a^2 \cdot \text{Var}(n_a) + c_b^2 \cdot \text{Var}(N_b) \\ &\quad + 2c_a c_b \cdot \text{Cov}(N_a, N_b), \end{aligned} \quad (19)$$

where $\text{Var}(N_a)$ and $\text{Cov}(N_a, N_b)$ is given in Equations (14) and (18) and $\text{Var}(N_b)$ can be obtained by a similar way for $\text{Var}(N_a)$.

Warranty Cost Analyses for Series Systems

In this section, warranty cost analyses are conducted by computing the expected warranty cost as well as the variance of the warranty for the series systems based on the interfailure intervals.

A component's reliability function is considered first. We investigate the reliability of each component and its interfailure interval using altered QRP. Let $f_{ij}(\cdot)$, $F_{ij}(\cdot)$, and $R_{ij}(\cdot)$ be the pdf, cdf, and reliability function of component j 's failure times after $(i-1)$ th repair/replacement within a warranty period w , respectively. The reliability function of the j th component and the i th interfailure interval using the altered QRP is as follows:

$$\begin{aligned} R_{ij}(w) &= 1 - \int f_{ij}(x) dx \\ &= 1 - \int \frac{1}{\beta_{ij}} f_{1j} \left(\frac{1}{\beta_{ij}} x \right) dx. \end{aligned} \quad (20)$$

Because there are q components in the series system, its system reliability can be obtained by multiplying each component's reliability. Each component's failure rate is assumed to be independent. Therefore, using Equation (3), the reliability function of the i th interfailure interval for the series system is given by

$$\begin{aligned} R_{is}(w) &= \prod_{j=1}^q R_{ij}(w) \\ &= \prod_{j=1}^q \left(1 - \int \frac{1}{\beta_{ij}} f_{1j} \left(\frac{1}{\beta_{ij}} x \right) dx \right). \end{aligned} \quad (21)$$

From Equation (12), we can obtain the pdf of series systems

$$\begin{aligned} f(n) &= \left(\prod_{i=1}^{n_s} (F_{is}(w)) \right) (R_{(n_s+1)s}(w)) \\ &= \left(\left(1 - \prod_{j=1}^q \left(1 - \int f_{1j}(x) dx \right) \right) \right. \\ &\quad \left. \times \prod_{i=2}^{n_s} \left(1 - \prod_{j=1}^q \left(1 - \int \frac{1}{\beta_{ij}} f_{1j} \left(\frac{1}{\beta_{ij}} x \right) dx \right) \right) \right) \end{aligned}$$

$$\times \left(\prod_{j=1}^q \left(1 - \int \frac{1}{\beta_{(n_s+1),j}} f_{1j} \left(\frac{1}{\beta_{(n_s+1),j}} x \right) dx \right) \right). \quad (22)$$

Using Equation (22), the expected number of warranty repair services is given by

$$E(N_a) = \int n_a \cdot f(n_a) \cdot dn_a. \quad (23)$$

We can easily derive the second moment as follows:

$$E(N_a^2) = \int n_a^2 \cdot f(n_a) \cdot dn_a. \quad (24)$$

Using the first moment and the second moment, the variance of the number of repair services is given by

$$\text{Var}(N_a) = E(N_a^2) - [E(N_a)]^2, \quad (25)$$

where $E(N_a)$ and $E(N_a^2)$ are given in Equations (23) and (24).

Additionally, the covariance of the repair services and the replacement services is given as follows:

$$\text{Cov}(N_a, N_b) = E[N_a N_b] - E[N_a]E[N_b]. \quad (26)$$

Using Equation (17), we also obtain

$$\begin{aligned} E[N_a N_b] &= \sum_{n_b=0}^{\infty} \sum_{n_a=0}^h \left(n_a n_b \left(1 - \prod_{j=1}^q \left(1 - \int f_{1,j}(x) dx \right) \right) \right. \\ &\quad \times \prod_{i=2}^{n_a+n_b} \left(1 - \prod_{j=1}^q \left(1 - \int \frac{1}{\beta_{ij}} f_{1,j} \left(\frac{1}{\beta_{ij}} x \right) dx \right) \right) \\ &\quad \times \prod_{j=1}^q \left(1 - \int \frac{1}{\beta_{(n_a+n_b+1)j}} \right. \\ &\quad \left. \left. \times f_{1,j} \left(\frac{1}{\beta_{(n_a+n_b+1)j}} x \right) dx \right) \right). \end{aligned} \quad (27)$$

Similarly, we can obtain the expected number of replacement services $E(N_b)$ and the variance of number of the replacement

service $\text{Var}(N_b)$. Using $E(N_a)$ and $E(N_b)$, the expected warranty cost for the series system is given by

$$E(C) = c_a E(N_a) + c_b E(N_b). \quad (28)$$

Combining Equations (25) and (26), the variance of warranty system cost is given by

$$\begin{aligned} \text{Var}(C) &= c_a^2 \cdot \text{Var}(N_a) + c_b^2 \cdot \text{Var}(N_b) \\ &\quad + 2c_a c_b \cdot \text{Cov}(N_a, N_b). \end{aligned} \quad (29)$$

NUMERICAL EXAMPLES AND SENSITIVITY ANALYSIS

In this section, a numerical example is presented to illustrate the analyses of system cost functions for the series system. We assume that the failure time of the system follows an exponential distribution with constant failure rate $\lambda = 1$. Given $q = 2$ (see Fig. 2) and $h = 1$. We assume that the warranty costs and β values are as follows:

$$c_a = \$5,000, c_b = \$8,000 \text{ and}$$

$$\beta_{i1} = 0.99, \beta_{i2} = 0.98.$$

The results are given in Table 1 including the expected warranty cost, $E(C)$, standard deviation, $\text{SD}(C)$, and coefficient of variation (CV) for various values of w .

In Fig. 3, the expected warranty cost increases as warranty time increases. When there exists a covariance between the repair and the replacement services, it can be seen that both the expectation and the standard deviation of warranty cost functions increase monotonically over the warranty period. It would be expected that the standard deviation in this particular case is larger than the expected warranty cost since the distribution of n is coming from a geometric distribution whose standard deviation is

always larger than the expected warranty cost. The CV is defined as the ratio of the standard deviation to the mean and describes the magnitude sample values and the variation within them. When they are independent, the CV has a v-shape curve as the warranty time progresses. When it decreases, it indicates smaller variations.

INTRODUCTION

Globalization poses challenges to current businesses. To keep costs down, many business firms have turned to outsourcing. By definition, outsourcing refers to the act “to procure (as some goods or services needed by a business or organization) under contract with an outside supplier” (Merriam–Webster Dictionary). Almost any business process can be outsourced: manufacturing, product design, procurement, customer care, or other services (see ***Supply Chain Outsourcing*** for an in-depth discussion). Various benefits have been reported that fuel the outsourcing growth. Early outsourcing deals focus on cost savings [1,2], but as Kakabadse and Kakabadse [3] note, recently the goal of outsourcing has shifted from cost reduction to value creation. The value additions found by researchers have included improved speed or quality of services [1], access to outside talent, innovation, and new technology, strategic alliances with outsourcing partners [1,2], focus on core missions [4], and greater flexibility [1]. For a detailed discussion on advantages and disadvantages of outsourcing, please see the article titled ***Business Process Outsourcing*** in this encyclopedia.

With information technology, many types of tasks that are traditionally performed in-house can now be outsourced [5]. Indeed, not only is outsourcing here to stay, it is also set to grow. Those projected to grow the fastest in

2008–2009—financial, legal, supply chain, medical, and news services—are all service functions [6]. A Gartner Group study has estimated that the overall global outsourcing market will grow by 8.1% in 2008 [7]. Anand and Aron [8] cite external studies that project that the off-shore business process outsourcing (BPO) industry will grow from \$123.6 billion in 2001 to over \$230 billion in 2015. A big portion of the service outsourcing activities are service related. It is estimated that, in the total US GDP, roughly 84% of value-added activities are service related [5]. Service outsourcing, therefore, plays an important role in the current and future US economic activities.

From a research perspective, however, operations management (OM) research on service outsourcing is less visible, compared with research in manufacturing and physical systems. In this context, we review OM research in the field of service outsourcing, and then discuss some future research opportunities. In particular, we focus on the following three research areas:

1. *Capacity Planning and Supplier Coordination in Service Outsourcing.* Probably the most prominent component in service outsourcing is to plan for adequate capacity. This can be difficult considering the uncertainty involved in a service system, and the heterogeneity in customer requirements and server capabilities. In addition, it requires coordination with the service provider, which in turn is dependent upon economic incentives. We will review papers in both areas, that is, those that analyze capacity systems and aim to improve capacity planning methods, and those that focus on incentives and coordination mechanisms.
2. *Service Outsourcing under Information Asymmetry.* A frequent problem that companies face in service outsourcing is that they lack perfect information

about their potential outsourcing partners. Recent researches have been successful in dealing with such a problem, which we review in depth.

3. *Quality Concerns in Service Outsourcing.* Currently, more and more attention is being paid to the potential pitfalls in service outsourcing. Quality concern is frequently cited as one of the greatest issues in outsourcing. We review researches that study this problem and highlight their findings that can help companies avoid the “quality trap” and maintain a high level of service quality when outsourcing.

Before we delve into reviewing individual papers, a note on the distinction between outsourcing and offshoring is in order. Offshoring refers to a change in location of service facilities, and does not necessarily entail sourcing from outside vendors. For example, companies may choose to setup and operate their own customer service centers in some other foreign countries. In comparison, outsourcing means contracting out business processes to an outside supplier, which may not be located offshore. Please refer to the article titled **Business Process Outsourcing** in this encyclopedia for more discussions and examples distinguishing the two terms.

LITERATURE REVIEW

Capacity Planning and Supplier Coordination

Capacity planning is a perennial topic in the OM service literature, and it is no exception in the OM outsourcing literature. In any outsourcing configuration, the capacity (and other things like effort) at both parties need to be planned and coordinated. This is very often done via a contract mechanism. In this part, many papers have to do with contracting issues in the context of call center outsourcing, but they all use different terminologies. To expedite the discussion, it is necessary to first introduce some common notations.

In a simple one-to-one call center outsourcing setting, two parties are involved: a firm (which we call the *user*) sends all or some of

its customer calls (or emails) to an outside call center (which we call the *vendor*). The vendor hires and trains its own agents to handle the calls, and each successfully handled call provides a direct benefit to the user firm (direct revenue or customer satisfaction). The contract then determines how much payment should be made from the user to the vendor. At the least a typical contract specifies scope of work, deliverables, terms and conditions, and service level agreement (SLA) [9]. Transfer payment can be calculated in a variety of ways. For example, a typical call center outsourcing contract involves at least some forms of pay per time (PPT) or pay per call (PPC) [10]. In the former arrangement, the user pays the vendor based on the agent hours that are spent. This is also referred to as *pay-for-capacity* [11]. In the latter arrangement, the payment is based on the number of calls that are handled. This is also referred to as *piecemeal* [12] or *pay-for-job* [11]. In practice, these contracts are often combined with other incentives or penalties based on call resolution [12], waiting time, or SLA achievement [13,14].

Ren and Zhou [12] and Hasija *et al.* [13] are concerned with the design of a coordinating contract. A contract is said to be *coordinating* if it achieves two goals in the decentralized setting: (i) it induces the vendor to choose system-optimal staffing and effort level (i.e., $s^v = s^I$ and $e^v = e^I$) and (ii) it allows for an arbitrary split of system profit between the user and the vendor. With a coordinating contract, both parties can first achieve the highest total profit, and then share it in such a way that each is better off than under a noncoordinating contract.

Consider the following model of such a simple one-to-one call center outsourcing supply chain. The vendor is modeled as a multiserver queueing system with customer abandonment. The arrival rate is λ , the service rate is μ , and the customer patience (i.e., time waiting in the queue until abandonment) has continuously differentiable PDF f and CDF F . The staffing cost rate is c_s , the customer waiting cost rate is c_w , and each time a customer abandons, there is a cost of c_a . Of the served calls, only a portion, p , are satisfactorily resolved. Each resolved

call results in a revenue of (representing direct sales, customer satisfaction, etc.), but incurs a loss of goodwill c_g for each resolved call (representing the reduction in both immediate and future sales). The resolution rate p is influenced by the agents directly, but ultimately determined by the vendor's effort level, which includes agent training, infrastructure development, technical support, and so on. The vendor's resolution $p(e)$ is assumed to be concave, increasing in its effort level e . The vendor bears the effort cost at a rate of c_e .

Therefore, the vendor must make two decisions: staffing level and effort level, and the user must determine the appropriate terms for the contract to induce the vendor to make system-optimal decisions.

The vendor's $G/GI/s + GI$ queueing model is hard to analyze. Even a simpler $M/M/s + M$ system is hard to analyze [15]. Ren and Zhou [12] follow a fluid approximation approach, which is shown to be remarkably accurate by Whitt [16]. In the fluid approximation, if the vendor's staffing level is s , then the system throughput rate, abandonment rate, and steady-state wait time are respectively, $T(s) = \min(\lambda, \mu s)$, $L(s) = \lambda - T(s)$, and $W(s) = \frac{L(s)}{f(0)\lambda}$ assuming $f(0) \neq 0$.

In the centralized (i.e., first-best) setting, the objective is to maximize total system profit:

$$\begin{aligned} \max_{s,e} \pi^I(s,e) = & rp(e)T(s) - c_s\mu s - c_e e - c_a L(s) \\ & - c_w\lambda W(s) - c_g(1 - p(e))T(s), \end{aligned} \quad (1)$$

and the optimal decisions are $s^I = \lambda/\mu$ and $p'(e^I) = \frac{c_e}{(r+c_g)\lambda}$, if $\frac{c_e}{(r+c_g)\lambda} < p'_0$; $e^I = 0$ otherwise.

In the decentralized outsourcing supply chain, the user offers the vendor a contract to take all of its calls. The vendor decides its staffing and effort levels, and, depending on the service outcome (e.g., T , W , L , etc.), it receives a payment Ψ from the user as specified in the contract. The user receives a revenue r from each served and resolved customer. Because the vendor is invisible to the customers, the user also bears all the costs of customer abandonment, customer waiting,

and unresolved calls. In such a setting, the vendor and user maximize their respective individual profit π^v and π^u :

$$\begin{aligned} \pi^v(s,e) &= E(\Psi) - c_s\mu s - c_e e, \\ \pi^u(s,e) &= rp(e)T(s) - c_a L(s) - c_w\lambda W(s) \\ &\quad - c_g(1 - \bar{p}(e))T(s) - E(\Psi). \end{aligned}$$

Ren and Zhou [12] find that a simple PPC contract, where $\Psi = bT(s)$, can coordinate the vendor's staffing level (i.e., $s^v = s^I$), but it fails to coordinate the vendor's effort level. In fact, the vendor will exert no effort (i.e., $e^v = 0$) at all because it pays for all the effort cost but receives no accordant benefit. A pay-per-call-resolved (PPCR) contract, where $\Psi = bp(e)T(s)$, also coordinates the vendor's staffing level (i.e., $s^v = s^I$). Although it lifts the vendor's effort level, it still falls short of the system-optimal effort level (i.e., $0 < e^v < e^I$). This is intuitive because, while PPCR rewards the vendor for its effort, the benefit resulting from a higher effort level is shared between the user and the vendor. On the other hand, the vendor bears the total cost of effort. This incentive misalignment is similar to the "double marginalization" observed in physical-goods supply chain. To remedy this, Ren and Zhou [12] propose two additional contracts—pay-per-call-resolved plus cost sharing (PPCR+CS) and partnership (PART)—that are shown to coordinate the supply chain (i.e., $s^v = s^I$ and $e^v = e^I$). Under the PPCR+CS contract, $\Psi = bp(e)T(s) + (1 - \alpha)(c_s\mu s + c_e e) - \alpha[c_g(1 - p(e))T(s) + c_a L(s) + \frac{c_w}{f(0)}L(s)]$. It basically lets the user share the vendor's costs so that overall the vendor's incentive is proportional to that of the supply chain. Furthermore, the vendor's share of the total profit is b/r . By varying b , the two parties can achieve a desirable share of the total profit. While PPCR+CS requires more information sharing, which may be difficult to do practically, PART requires less information sharing: the vendor pays the user for each customer arrival but gets to keep all the revenue. In addition, the user shares part of the vendor's staffing cost and gives it a fix effort compensation based on the system optimal e^I : $\Psi = rp(e)T(s) - (1 - p(e))c_g T(s) - (1 - \alpha)[rp(e^I) -$

$c_g(1 - p(e^I))T(s) + (1 - \alpha)c_s\mu s + (1 - \alpha)c_e e^I - \alpha\left(c_a + \frac{c_w}{f(0)}\right)L(s)$. In essence, PART has the flavor of a franchise arrangement.

Instead of the fluid approximation, Hasija *et al.* [13] use an $M/M/N + M$ queueing system to model the vendor's call center and find that neither a PPC nor a PPT contract can coordinate the vendor's staffing level. This difference is due to the fact that, while it is advantageous to be at 100% utilization level in a fluid system, in a queueing system, system utilization must stay strictly below 100% and customer abandonment is convex increasing in the utilization. However, Hasija *et al.* [13] show that by adding additional penalty for violating service level agreements the enhanced PPC and PPT contracts can coordinate the outsourcing chain.

In addition, Hasija *et al.* [13] study the effect of information asymmetry. Specifically, the vendor's effort level is private information, and as a result the user does not know whether the vendor has a high or low productivity (i.e., service rate). In such a case, an optimal contract will have to additionally induce the vendor to self-select and reveal its productivity type. The authors show that coordinating contracts in the full-information case may no longer be optimal. Instead, the authors propose several specific combinations of PPT and/or PPC contracts with additional constraints (e.g., average service time limit, SLAs, and/or wait time penalty) and show them to be optimal. In addition to achieving maximum profit for the system, the authors also discuss how profits can be allocated between the user and the vendor under such contracts.

Milner and Olsen [17] demonstrate the importance of selecting the right SLA and setting the right parameter. It studies a call center outsourcing situation where the vendor handles work not only from the user under a contract but also from other noncontract sources. The vendor call center system is modeled as a multiserver queue and the user requires the vendor to satisfy a constraint on delay percentile (i.e., the percentage of delay that exceeds a limit). To the extent that the vendor has more capacity than necessary, it will also take noncontract work to increase revenue. The problem for

the vendor then becomes how to prioritize calls from these two different sources: the vendor wants to minimize the average wait time for the noncontract jobs, subject to the delay percentile constraint for the contract jobs. Using the heavy traffic regime, where system load approaches 1, as an approximation to the original system, the author shows that it is optimal to use a two-threshold policy where contract jobs are given priority only if the queue length is neither too long nor too short. This result has implications for both the user and the vendor. For the user, even though the delay percentile constraint in the contract is satisfied, the two-threshold policy could seem unfair because contract jobs will be given lower priority when the queue is long. The authors then suggest that the user should add more constraints to the contract, or impose a convex penalty on excess delay (which makes it optimal for the vendor to use a fairer single-threshold policy). Several other contract forms were also studied and found inadequate.

While these three papers study contract issues in a complete outsourcing setting, where the vendor handles all of the user's customer calls, Akş in *et al.* [11] study contract issues in a cosourcing setting where the user outsources only some, but not all, of its calls to the vendor for strategic (customer segmentation) or operational (call volume uncertainty) reasons (this term is also described in Willcocks and Lacity [18]). Cosourcing is often promoted as an alternative to complete outsourcing [19]. Demand at a call center—the call volume—is uncertain and fluctuating in nature, as is the demand at most services. The forecasted call volume pattern can be broken into two parts—the base volume (which is a stable volume over time) and the fluctuation (anything above the base). It is easy and cost effective to staff to the base call volume. However, to achieve any reasonable service level, call centers must plan extra staffing to deal with the fluctuation. In a cosourcing setting, an important question becomes which contract type—contracting the base or contracting the fluctuation—is a better one. Specifically, in the former setting, the user's would staff just enough to deal with the stable base demand, while the vendor

would have to carry safety capacity to handle the fluctuation. (Since the vendor is paid by the volume, this contract takes the form of PPC.) In the latter setting, the vendor is responsible for the base and the user handles any fluctuation above the base. The vendor therefore will set a stable staffing level to handle the base and be compensated by PPT.

On the surface, the user should prefer to keep the base because of the lower in-house staffing cost it entails. However, the vendor's optimal charge will be different in the two settings. Overall, Akşin *et al.* [11] are able to characterize the optimal capacity levels and partially characterize the optimal prices under both contract types. Because the vendor optimally charges different prices under different contracts, neither contract type dominates for the user. The contract choice depends on the call fluctuation patterns in addition to the revenue and cost parameters.

Two more papers, Gans and Zhou [10] and Koçağa and Ward [20], deal with the cosourcing arrangement, but they eschew the contracting issues and focus on real-time call-routing decisions instead.

Gans and Zhou [10] consider the operational-level coordination issues in a call center cosourcing arrangement where calls of high value are often kept "in-house" by the user and the low-value calls are outsourced. Since the customer service representatives often receive nested skill training, those handling high-value calls are also capable of handling low-value calls. This presents the user a chance to use idle in-house, high-value representatives to handle low-value calls opportunistically. This helps the user firm to lower the volume of outsourced calls and hence cost. The authors present four coordination schemes differing in their routing sophistication and coordination/communication requirements. Assuming identical service time distribution of low- and high-value calls, they show that a relatively simple routing scheme can perform nearly optimally in large systems. This scheme also has the added benefit of not requiring extensive coordination between user and vendor firms on a real-time basis. In small systems, however, it is necessary to

use a threshold-type routing policy—using in-house high-value representatives to take low-value calls only when idle capacity exceeds a certain threshold.

In Koçağa and Ward [20], the user operates its own call center but, when the call center is congested, customers abandon due to long waits. In such cases, it is worthwhile to route calls to an outside vendor. A natural trade-off occurs between call abandonment and outsourcing cost. The paper formulates a Markov decision process model and shows that a queue-length-based threshold policy is optimal. Because this policy is complicated, the authors also propose a diffusion approximation and calculates the optimal threshold. Numerical analysis reveals that the diffusion approximation is very accurate and optimally utilizing the outsourcing option can yield significant cost savings.

While all the papers discussed so far deal with one-level service processes, Lee *et al.* [14] study contract issues in the outsourcing of a two-level service process. When all the customers first arrive, they are handled by first-level agents (who are called *gatekeepers*). Because customers are heterogeneous, the agents first diagnose the difficulty of each request. When the difficulty level is below a threshold k , the gatekeepers further proceed to treat these customer requests. This is successful only with probability $F(k)$. Customer requests with difficulty level above k are passed on (along with those unsuccessfully treated by the gatekeepers, called *mistreatment*) to a second-level group of agents (called *experts*). The experts then successfully handle all the requests. Staffing, as well as customer waiting, on both levels incur costs. The mistreatment by the gatekeepers also incurs a further cost. Using a Halfin–Whitt approximation [21] to staff both levels, the authors find the optimal first-best staffing levels and the optimal threshold k^* . They then show that (i) when only the expert level process is outsourced, a PPC+WP contract (where WP indicates additional linear penalty for waiting time) coordinates the systems, (ii) when only the gatekeeper level process is outsourced, a PPC+PPT+WP contract coordinates the system, and (iii) when both

levels are outsourced, a PPC+PPT+WP+ST contract (where ST indicates additional linear payment for successful treatments) coordinates the system *only if* system parameters satisfy certain condition.

Service Outsourcing under Information Asymmetry

Both parties involved in an outsourcing arrangement do not share all of their private information with each other. How does this information asymmetry affect the contract design, and what is the impact of such information asymmetry? Four papers address this question.

As we previously reviewed, in Hasija *et al.* [13], the vendor's effort level is private information not shared with the user. The authors show that, to achieve coordination, the contract in this setting is more complicated than that with full information. Additional SLAs or penalties must be added and only particular combinations of PPC and PPT contracts can coordinate.

Akan *et al.* [22] examine call center outsourcing contract design under a different kind of information asymmetry: the user firm has private information about customer call demand (high or low), while the vendor only has a prior belief of its distribution. When it is the vendor who offers the contract, the authors show that the optimal screening contract offers too low an abandonment probability to the high-type user (as compared with the first best) but offers no such distortion in the abandonment probability to the low-type user. This result contradicts the "efficiency at top" results in the literature on monopolist screening, and is largely due to the use of the queueing systems. When it is the user who offers the contract, the low type will offer the same abandonment probability as in the first best case, but the high type offers an abandonment probability below the first best, and has to pay more for each call. These distortions, however, can be mitigated and even removed by a two-part tariff contract—in addition to the per call charge, the user also makes a fixed payment to the vendor.

Ren and Zhang [23] examine call center outsourcing contract design when the user

does not know the vendor's capacity cost or quality cost. In many situations, when a vendor's service quality is high—be it service speed, or problem resolution rate—it tends to be more expensive as well. In the call center industry, for instance, labor costs are typically lower for call centers located overseas, compared to those located in the United States. However, the service quality for domestic call centers is often much higher. In some situations, the two costs may be positively correlated. For example, successful quality improvement initiatives may simultaneously bring down the capacity and quality costs of a firm. Ren and Zhang [23] study service outsourcing where the vendor exhibits such correlations. In their model, a user plans to outsource with an outside vendor, but it has no information about the vendor's capacity cost or quality cost (i.e., how hard it is for the vendor to reach a certain service level). However, the user does know the correlation between the two costs. Such information is usually obtainable through market research. The authors show that the form of the optimal outsourcing contract depends critically on the relationship between capacity and quality costs. They also study the effectiveness of simple contracts, contracts that are not contingent upon information unknown to the user. They find that those noncontingent contracts perform well when the correlation between capacity cost and quality cost is positive, but they can perform much worse when the correlation is negative.

Finally, Plambeck and Zenios [24] study a dynamic principal-agent model where the principal outsources work to the agent but the agent's effort is unobservable. Their model can be motivated by the so-called *maintenance problem*. A machine generates profits, but its owner delegates its maintenance to a manager, who has to repair the machine when it breaks down. The owner cannot observe the manager's effort in repairing the machine, and can only observe if the machine is functioning or not. Therefore the owner's problem is to design a performance-based contract that will motivate the manager to take actions that maximize the owner's profits over a finite horizon. Their model is applicable to similar situations in

service outsourcing, where the actions of the outsourced services are not observable, and only their outcomes are observed.

Quality Concerns in Service Outsourcing

One of the key considerations in service outsourcing is assuring high service quality by the vendor. As we stated in the introduction, firms are increasingly focusing on the quality benefits of outsourcing rather than the cost benefits. Three papers deal with the quality aspect of outsourcing.

As we reviewed before, Ren and Zhou [12] examine how contracts can be used to effectively ensure optimal service quality level by the vendor. They show that simple contracts, even the pay-per-call-resolved contract that takes quality into consideration, do not coordinate the vendor's quality training effort level. Instead, more complex contracts are needed. In this article, quality is measured by the call resolution rate achieved by the vendor.

Benjaafar *et al.* [25] study how firms should go about outsourcing to their vendors with service quality considerations. Below, we describe their model in a service outsourcing setting, even though it applies to both service and inventory systems. They compare two scenarios. The first is to allocate demand among a set of vendors, but the proportion of demand that each vendor gets is an increasing function of the service level of each vendor. Here service level is measured by customer waiting time, abandonment probability, and so on. They call this approach supplier-allocation (SA) approach. The other, called the *supplier-selection* (SS) approach, uses a probability to select one vendor. The probability of being selected is an increasing function of service level committed by the vendor. They find that often using just one vendor (i.e., the SS approach) is advantageous, but such an advantage depends upon the form of cost functions of serving customers incurred by the vendors. Moreover, by selecting an appropriate allocation mechanism, the user can indeed induce a higher service level provided by its vendors.

Cachon and Zhang [26] study a queueing model with one user and two vendors. The

user could orchestrate a service competition by allocating demand based on the vendors' performance, which is measured by speed of service. But how? The authors consider a variety of allocation policies, starting from state-independent policies that minimize the user's lead time given fixed capacities and nonstrategic vendors. They then move on to more complex state-dependent policies, and find that the variation in performance across different allocation policies is wide. Moreover, they show that there exists an allocation policy that can induce maximum vendor speed and at the same time minimize the user's lead time. Therefore, there need not be a trade-off in incentive and efficiency in outsourcing.

In the ride share model studied by Li *et al.* [27], the service level is measured by the percentage of demand that is denied. BostonCoach Inc. is a premier provider of executive sedan, limousine, and event transportation services. Not unlike the call centers, it has a relatively inflexible fixed capacity, yet its demand is random and fluctuating: in the Boston area, on a typical day, only about 85% of its demand is booked one day in advance. If BostonCoach projects to have insufficient capacity, it can subcontract with its collaborating companies (thus this is a cosourcing arrangement), but this has to be done one day ahead. That is, the overall capacity (own capacity plus contracted capacity) must be decided one day ahead. In real time, if, on the day of service, demand is much higher than expected, then requests will be denied, resulting in significant ill-will cost. The authors develop a model that incorporates various demand features (origin-destination, time window, specific vehicle and/or driver request, and trip type) and capacity constraints (driver availability, shift constraints, driver/vehicle pairing, etc.). A math program is devised to minimize the total cost and a column-generation method is adopted to solved it. Results show that using the proposed method can significantly improve the productivity of existing fleet. This results in reduced percentage of denied services, reduced use of drivers, and reduced use of contract services.

CONCLUSION AND FUTURE RESEARCH DIRECTIONS

In this article, we aim to give an overview of the current status of OM research in service outsourcing. Currently, the number of papers in this area is not large but we expect the area to grow over time.

Several areas are promising for future research:

- Outsourcing vendor selection is a difficult but important topic. Owing to the uniqueness of services being outsourced and the difficulty of measuring and monitoring various aspects of service quality, switching vendors is a process that involves significant cost and time. The current service outsourcing contracting papers have focused on one-shot games. Clearly, it would be interesting and helpful to study the use of repeated-game models and other more complex contract structures (for an example of the use of repeated game in a supply chain context [28]).
- Most services are complex, multiple-stages processes. Outsourcing decisions do not have to be all-or-nothing. Two directions are worth pursuing: (i) The user can choose to outsource some stages of the service process while keeping the rest in-house, but the current papers, with the exception of Lee *et al.* [14], are all concerned with the outsourcing of a single-stage process. The choice of what to outsource, how to outsource, and how to coordinate the stages that are outsourced with those that are not are all interesting areas for future research. (ii) Even after the user has decided what to outsource, there is still the question of how much to outsource. Cooutsourcing, as we review above, is a useful arrangement. More research is needed to shed light on its effective use.
- Other types of information asymmetry, such as private demand forecasts, are worth studying. In service outsourcing, the vendor often has to make

capacity decision with only a rough estimate of future demand, while the user may have better information. Hence, depending on specific situations, the user may have an incentive to overforecast demand to the vendor, causing costly capacity overinvestment. How to induce truthful behavior from the user and achieve the maximum system efficiency is an interesting topic. Similar problems have been studied in the context of supply chain management. Interested readers are referred to Cachon and Lariviere [29].

- On a more technical level, the difference in the results obtained by Ren and Zhou [12] and Hasija *et al.* [13] is due to the different queueing models they choose (the fluid model in Whitt [16] and the diffusion model in Garnett *et al.* [15]). Therefore, much work still needs to be done to understand the impact of using different queueing models and approximation methods. Interested readers are referred to Ward Whitt's and Avi Mandelbaum's research web pages¹.

Since there already exists a large literature on information technology outsourcing (ITO), it is also beneficial for OM researchers to learn about the other aspects of outsourcing that we have not covered in this article. Dibbern *et al.* [30] give an excellent and comprehensive review of the IS outsourcing literature. We have touched upon several relevant topics in this article, but interested readers are highly encouraged to read [30]. Although they only review the ITO literature, we believe the methodologies and frameworks apply to other outsourcing settings, including service outsourcing.

Finally, we fully expect research in the areas of personal, legal, medical, and other professional service outsourcing to

¹<http://www.columbia.edu/~ww2040/allpapers.html> and <http://iew3.technion.ac.il/serveng/References/references.html> respectively.

grow rapidly, along with the increasing use of outsourcing in these areas in practice.

Cooperation among companies is widely practiced today in different business sectors. Facing increasing pressures to improve profitability, companies are responding by seeking and implementing solutions that require strategic collaboration with external partners because these solutions afford benefits that cannot be achieved alone. In the transportation industry, cooperation occurs among both the buyers of transportation services, that is shippers, and the suppliers of transportation services, that is carriers. For example, Elemica [1] coordinates and jointly procures truckload transportation services for more than 2000 companies in the chemicals industry creating a balanced transportation network due to *economies of scope*. Less-than-truckload (LTL) operations, where the carriers (truck companies) collect and bundle freights from various shippers to transport from one breakbulk terminal to another, can also be regarded as an implicit collaboration among shippers creating savings due to *economies of scale*. Such operations enable shippers to enhance their overall shipping efficiency by sharing truck capacity, resulting in increased capacity utilization and decreased deadheading. This,

in return, reduces the shippers' individual transportation costs as well.

On the carriers' side, alliances are formed in many modes of transportation, especially those with regularly scheduled service routes. For example, the first modern air cargo alliance, SkyTeam Cargo, was formed in 2000 by Aeroméxico Cargo, Air France Cargo, Delta Air Logistics, and Korean Air Cargo. According to the published figures, the two main air cargo alliances, WOW Cargo and SkyTeam Cargo, accounted for about 20% [2] and 17.5% [3,4], respectively, of the total air freight traffic in freight ton kilometers in 2003. Members of an alliance usually collaborate by integrating their operating networks into an extended and better load-balanced one, which is more profitable and has a reduced cost of fleet idling. The infrastructure setup costs, such as equipment and administrative costs, are often shared as well, providing more incentives for individual carriers to join an alliance.

Collaboration among shippers and among carriers plays a key role in the current cargo transportation industry and will serve as a future trend as it facilitates more efficient and cost-effective operations. However, many challenges are posed in the management of carrier alliances and collaborative procurement networks as they are typically composed of entities driven by selfish interests. In this article, we provide an overview of how to design and manage collaborative initiatives so that both the overall efficiency and the stability of the collaboration is guaranteed. To this end, we discuss the following three management mechanisms, differing from each other in the levels of coordination and information sharing required among the collaborating entities as follows:

1. We first consider a *centralized* model where a central authority is assumed to run the overall business operations and then distribute the revenues or costs among the members. Individual members have the option of breaking

away from the collaboration if their net benefits are undermined. Our goal is to evaluate the maximum potential benefit from collaboration by solving for the centralized system optimal solution, and to allocate the benefit in a fair way. Such a setting is relevant, for example, in collaborative transportation procurement networks where there is a centralized entity such as Elemica that serves as the centralized overseer.

2. Most carrier alliances function as *decentralized* systems where each carrier operates its own assets and makes its own routing decisions. Therefore, we next consider mechanisms where a centralized authority only designs the rules of interaction for the individual entities in order to elicit a solution out of individual decisions that is both socially efficient and beneficial for individuals. Specifically, as most carrier alliances are formed primarily for pooling fleet capacity, one natural approach is to establish capacity-sharing mechanisms, for example, unit prices for capacity exchanges.
3. Finally, we consider *auction* mechanisms that are widely adopted for the management of procurement of transportation services, especially when there is a large number of carriers and the market is fragmented (such as in the US trucking industry [5]). In such settings, procurement auctions can be used to implicitly coordinate the actions of the individual buyers and sellers. We discuss the design of auctions in order to reveal true information from the bidders and thus, to obtain a socially efficient outcome.

Note that the level of coordination and information sharing decreases as we go from centralized operations and cost or benefit allocations, to exchange mechanisms where there is a limited centralized control amounting to establishing rules and prices for the exchanges, and finally to auction mechanisms where synergies get exploited by the evolution of user bids. However, as the coordination and information sharing

requirements decrease, the computational burden on individuals for making optimal decisions increases. Moreover, the guaranteed system efficiency may also decrease as the degree of centralized control decreases.

Since the analysis of the approaches that we will address in the rest of this article largely depends on basic game theoretic concepts, we introduce these concepts in the following section.

GAME THEORY BASICS

Cooperative Game Theory

The field of *cooperative game theory* studies the interactions of selfish participants in a collaboration and provides a set of mathematical tools and concepts to study the “fair” distribution of costs and benefits. Specifically, a *cooperative game* is defined by a set N of players, referred to as the *grand coalition*, and a *characteristic function* $\mathcal{V}: 2^N \rightarrow \mathbb{R}$. The function $\mathcal{V}$ maps a value $\mathcal{V}(S)$ to every subset/subcoalition $S \subset N$, interpreted as the total benefit that the members of S can achieve by cooperating among themselves. We assume that $\mathcal{V}(\emptyset) = 0$. The central issue in cooperative game theory is how to allocate the total gain $\mathcal{V}(N)$ among the individual players $i \in N$ in a “fair” way to sustain the long-term stability of the grand coalition. One of the most prominent and widely accepted notions of fairness is the “core” of the game. A payoff allocation in the core represents a very strong type of stability that is not threatened by the defection of subcoalitions. However, frequently the core of a general cooperative game is empty. Mathematically, a payoff vector $x \in \mathbb{R}^{|N|}$, where x^i is the payoff to player i , is said to be in the core if

$$\sum_{i \in N} x^i = \mathcal{V}(N) \quad (\text{budget balance property}), \quad (1)$$

$$\sum_{i \in S} x^i \geq \mathcal{V}(S) \quad \forall S \subset N. \quad (\text{stability property}). \quad (2)$$

Some other important concepts regarding the *fairness* of benefit allocations from cooperative game theory include the stable

set, the nucleolus, and the Shapley value. We refer to Young [6] for a thorough review of basic cost allocation methods and to Borm *et al.* [7] for a survey of cooperative games associated with operations research problems.

Mechanism Design

Given a set of players N and a set $\mathcal{O}$ of possible outcomes for these players, let $v^i(o)$ be the valuation of an outcome $o \in \mathcal{O}$ for player i . Generally, we assume that each individual player aims to optimize his/her total payment. The goal of *mechanism design* is to design an algorithm that chooses an outcome $\tilde{o} \in \mathcal{O}$, and an n -tuple of side payments $\{s^1, \dots, s^n\}$ such that the total payoff to player i , x^i , calculated as $x^i = v^i(\tilde{o}) + s^i$, makes the outcome $\tilde{o}$ attractive to the individual players. Intuitively, mechanism design is concerned with determining both an algorithmic ingredient (to obtain the desirable system outcome) and a payment ingredient that motivates the players. This field has received widespread attention recently and has been used successfully to develop algorithms and protocols for interconnected collections of computers such as on the Internet. For a detailed discussion of mechanism design we refer the reader to Nisan and Ronen [8].

CENTRALIZED COLLABORATION MECHANISMS

In the centralized collaborative settings we assume that all information, assets, and operational decisions are handed over to a centralized authority and in return, the system is able to exploit synergies fully and promises a fair allocation of benefits and costs to individuals.

Such centralized carrier and shipper collaborations can generally be represented as cooperative games called (*multicommodity network flow games*) where the individuals own the commodities to be shipped between two given nodes for a revenue, as well as the capacities on the edges which will be used for the shipments. The concept of *flow games* is introduced by Kalai and Zemel [9,10], who

study centralized cooperation on networks with a single commodity where each arc is owned by a unique player. Derks and Tijs [11] extend the earlier results by studying multiple commodities with a common source–sink pair. More recently, Markakis and Saberi [12] study the coalitional multicommodity game in which players are the nodes of the given network who own capacity in terms of the maximum flow allowed through that node. Based on flow game models, the centralized authority generally can obtain the best system solution by solving a (multicommodity) flow problem on the given integrated network. The network flow models also facilitate the allocation of the revenue generated by the system completely and fairly so that no individual or groups of individuals defect from the collaboration.

Problem Definition

We define the maximum multicommodity flow (MCF) game as follows: let $G = (V, E)$ be a directed graph on a set of nodes V and a set of edges E which represents the entire transportation network in consideration. Let N be the set of shippers or carriers serving as players of the game. Each player $i \in N$ has a demand set D^i where $d_{(o,d,i)}$ denotes the maximum amount of existing demand from node o to node d for player i and $r_{(o,d,i)}$ denotes the revenue generated by delivering a unit of this demand. In the multicommodity setting, each demand triplet (o, d, i) represents a different commodity. Each edge $e \in E$ has a capacity c_e , which denotes the maximum amount of flow, summed over all commodities, allowed on that edge. γ_e^i denotes the fraction of capacity that player i owns on edge e , and $\sum_{i \in N} \gamma_e^i = 1$. For any set $S \subset N$, including N itself, we associate with it the value $\mathcal{V}(S)$ which equals the maximum revenue generated through the network owned by players in the set S . Such a value can be computed by solving a maximum MCF problem defined by the following linear program (P^S):

$$(P^S): \quad \mathcal{V}(S) = \max \sum_{(o,d,i) \in \bigcup_{i \in S} D^i} f_{(d,o,i)}^{(o,d,i)} r_{(o,d,i)} \quad (3)$$

$$\begin{aligned}
& \text{such that } \sum_{\{e:e \in IEdges(v)\}} f_e^{(o,d,i)} \\
& - \sum_{\{e:e \in OEdges(v)\}} f_e^{(o,d,i)} \leq 0 \\
& \forall v \in V \quad \forall (o,d,i) \in \bigcup_{i \in S} D^i \quad (4) \\
& \sum_{(o,d,i) \in \bigcup_{i \in S} D^i} f_e^{(o,d,i)} \leq c_e \sum_{i \in S} \gamma_e^i \quad \forall e \in E \quad (5) \\
& f_{(d,o,i)}^{(o,d,i)} \leq d_{(o,d,i)} \quad \forall (o,d,i) \in \bigcup_{i \in S} D^i \quad (6) \\
& f \geq 0. \quad (7)
\end{aligned}$$

In (P^S) , the variables $f_e^{(o,d,i)}$ denote the amount of flow of commodity (o,d,i) on edge e for each commodity (o,d,i) owned by members within S . $IEdges(v)$ denotes the set of incoming edges into node v and $OEdges(v)$ denotes the set of outgoing edges from v . The objective function (3) maximizes the revenue obtained by satisfying commodity demand. Constraint (4) is a flow balance constraint at every node of the network with respect to each of the commodities. Constraint (5) is a capacity constraint on each edge and constraint (6) is a demand constraint for every commodity. The optimal solution to (P^S) represents the flow that maximizes the revenue generated within the subcoalition S .

An outcome of the MCF game defined above consists of a feasible multicommodity flow, subject to demand and capacity constraints that maximizes the overall revenue generated. We next discuss how solving P^S also provides an allocation, $x \in \mathbb{R}^n$, of the resulting total revenue, that is $\mathcal{V}(N)$, among the players.

An Allocation in the Core

For cooperative games where the values of subcoalitions are computed via linear programming (LP) techniques, utilizing the dual optimal solution to the grand coalition's optimization problem is a common strategy to obtain an allocation for the players. Owen [13] shows that for linear production games where the LPs that are used to solve for

values of subcoalitions follow a regular pattern, such a dual scheme provides an allocation in the core. Kalai and Zemel [10] show that for simple networks, that is single commodity networks where each edge has a single unit of capacity and is uniquely owned, every core allocation corresponds to an optimal dual solution for the corresponding optimization problem. Deng *et al.* [14] provide an extension of Kalai and Zemel [10]. In the MCF game scenario, the dual payoff vector is defined as $x^i = \sum_{e \in E} \alpha_e^* c_e \gamma_e^i + \sum_{(o,d,i) \in D^i} \beta_{(o,d,i)}^* d_{(o,d,i)}$ where $\alpha^* = \{\alpha_e^* : \forall e \in E\}$ and $\beta^* = \{\beta_{(o,d,i)}^* : \forall (o,d,i) \in \bigcup_{i \in N} D^i\}$ are the optimal dual solutions associated with constraints (5) and (6) of the program (P^N) respectively.

Theorem 1. [15]. *The core of the MCF game defined in the section titled “Problem Definition” is nonempty and a payoff allocation in the core can be constructed in polynomial time by solving the dual program to the LP (P^N) . However, the core of this game is not generally fully characterized by these dual solutions.*

The fact that the core of the MCF game is not fully characterized by the dual payoffs is largely due to the generality of the game where no specific conditions are required in terms of either the network structure or individual capacity ownership levels. This fact not only motivates further research for understanding the elements in the core that are not driven from the dual payoffs, but also poses additional challenges in understanding the mechanisms that induce fair allocations (refer to Gui and Ergun [16] for details).

Applications

An Example. Figure 1 illustrates a time-expanded air-cargo alliance network with two capacitated edges (edges (1,3) and (2,4)) that represent flights operated by carrier A. The capacity on each of these edges is one. Edge (1,2) and (3,4) are ground edges, representing the ability of a load to wait in a location over time and therefore, have unlimited capacity. The per-unit revenues and the sizes of the loads are described in Table 1. The unique

Figure 1. Alliance network for allocation example.

Table 1. Loads for Allocation Example

Demand	Per-Unit Revenue ($r^{(o,d,k)}$)	Size ($d^{(o,d,k)}$)
(1, 3, A)	2	1
(2, 4, A)	2	1
(1, 4, B)	6	1
(2, 4, C)	3	1

centralized optimal solution is to deliver load (1, 4, B) using leg (1, 3) and ground edge (3, 4), and to deliver load (2, 4, C) using leg (2, 4), which generates a total revenue of 9. The optimality of this solution can be confirmed by solving the centralized LP (P^N) for this example. A subset of allocations in the core to carriers A, B, and C can then be characterized by $[\alpha_{(1,3)}^* + \alpha_{(2,4)}^*, 6 - \alpha_{(1,3)}^*, 3 - \alpha_{(2,4)}^*]$ where $\alpha_{(1,3)}^*$ and $\alpha_{(2,4)}^*$ are the optimal dual solutions with respect to edges (1, 3) and (2, 4) respectively, and thus must satisfy $\alpha_{(1,3)}^* \in [2, 6]$ and $\alpha_{(2,4)}^* \in [2, 3]$. For example, the dual solution in which $\alpha_{(1,3)}^* = 2$ and $\alpha_{(2,4)}^* = 2$ leads to the core allocation of $x^A = 4, x^B = 4$, and $x^C = 1$.

Other Applications of Cooperative Game Theory to Network Flow Problems. Flow game models have been widely adopted to analyze interactions of selfish entities in network collaborations under various practical contexts. There exists a set of papers that join cooperative game theory and classic network flow problems, such as Ergun *et al.* [17] and Özener and Ergun [18], which consider the centralized operations and cost allocations of the shipper collaboration based on the lane covering problem (LCP); Sanchez-Soriano *et al.* [19], which studies transportation games where shippers and

carriers are disjoint sets; Granot *et al.* [20], which analyzes delivery games that are associated with the Chinese postman problem; Derks and Kuipers [21], which studies routing games; and Tamir [22], which considers continuous and discrete network synthesis games. These papers in general study the existence of cost allocations with well-studied properties from cooperative game theory and propose computational procedures for finding such allocations. In addition, Song and Panayides [23] make use of cooperative game theory and provide a quantitative study to analyze liner shipping alliances by considering two small examples (involving 3 ports and 2–3 carriers). The costs and benefits are allocated among the alliance members in proportion to the shipping capacity each provides. However, in many situations a proportional allocation of benefits is not guaranteed to provide a payoff to the alliance members that is sufficient to sustain the stability of the collaboration. Moreover, network-related games such as the network design game of Kubo and Kasugai [24], the assignment game of Shapley and Shubik [25], and facility location game of Goemans and Skutella [26] have also been studied in the literature. Here, we provide detailed descriptions of two fundamental applications to classic network problems, the traveling salesman games (TSG) and vehicle routing games (VRG), which have been extensively discussed in the literature.

The TSG considers the problem of allocating the cost of a round trip among the cities visited. Depending on the game, there may exist a home city which is not included in the set of players. Tamir [27] considers a TSG with a home city and proves that under a symmetric cost structure, the TSG always has a nonempty core when the number of players is less than or equal to four. Kuipers [28] extends this result to a TSG with five players. Note that the core may be empty when the number of players is greater than or equal to six. Potters *et al.* [29] discuss the TSG and its variant with fixed routes. For the fixed route TSG where for all coalitions the cities are visited in the same order, they prove that the game has a nonempty core if

the fixed route solution is the optimal solution to the original TSP and the cost matrix satisfies the triangle inequality. They also introduce a class of matrices that generates TSGs with nonempty cores. Engevall *et al.* [30] consider the cost allocation problem of a distribution system of a gas and oil company where the total cost of a tour is to be allocated among the customers that are visited. Besides the well-known concepts regarding fair allocations from cooperative game theory, such as the nucleolus and the Shapley value, they introduce the “demand nucleolus,” which is similar to the nucleolus except that the excess of a coalition is multiplied by the demand of that coalition. By doing this, they aim to reduce the importance of coalitions that have relatively larger demands in computing the nucleolus.

The VRG considers the problem of allocating the cost of optimal vehicle routes among the customers served. Gothe-Lundgren *et al.* [31] consider the VRG with a homogeneous fleet and present conditions when the core of a VRG is nonempty. Then, they use a constraint generation approach to compute the nucleolus of a VRG with a nonempty core. Engevall *et al.* [32] extend this result to a VRG with heterogeneous vehicles with some simplifications, for which they study the existence of allocations in the core.

Although centralized systems are very efficient as one decision maker can choose the optimal solution for the collaboration and allocate the overall benefits in a fair manner so that the collaboration is stable, in many settings designing fully centralized systems is not realistic. In fact, real-life applications of network collaborations tend to be decentralized to a certain extent, as network users typically make decisions regarding their own commodity routing and capacity management. Hence, the incentives within the system must be designed in such a way that the individual players are motivated to participate in the grand coalition and choose solutions that are collectively optimal for the collaboration; that is, the revenue obtained is close to the maximum level that can be achieved within a fully centralized system. We present a detailed discussion of the management of shipper and carrier

collaborations under partially decentralized settings in the next section.

EXCHANGE MECHANISMS

In this section we focus on mechanisms that facilitate cooperation among participants in a decentralized setting through the exchange of network resources. We will primarily focus on exchanges among carriers. Given the decentralized setting, an important consideration of work in this area is that the entities that are collaborating (i.e., carriers and/or shippers) are autonomous and self-optimizing. Mechanisms which seek to influence behavior therefore must ensure that each entity stands to benefit by making the desired decisions.

The majority of work related to exchange mechanisms in collaborative transportation has been focused on settings in which carriers collaborate by sharing capacity. In general, the goal of these mechanisms is to encourage carriers to make decisions such that the welfare of the collaboration as a whole (i.e., the alliance or grand coalition) is optimized. Agarwal and Ergun [15] explore a general multicommodity flow cooperative game in which multiple players may own the capacity on each edge in the network. The proposed mechanism solves an inverse optimization problem (i.e., a modified dual problem in which every feasible solution satisfies complementary slackness conditions with a desired primal solution determined *a priori* [33]) to establish prices that players pay for the use of capacity which they do not own. The authors show that the prices always encourage players participating in the cooperative game to make capacity and routing decisions that are optimal for the grand coalition. However, it is only for the special case in which every edge is uniquely owned that the resulting allocation is guaranteed to lie in the core of the game. Gui and Ergun [16] expand on this work by examining conditions in which a core allocation can be guaranteed even when every edge in the network is not uniquely owned. A key finding is that the relationship between allocations obtained using the mechanism developed in Agarwal and Ergun [15] and the core is influenced by the presence of excess network capacity. Specifically,

in a congested network the mechanism will always yield prices that lead to an allocation in the core, even when edges are not uniquely owned.

A number of mechanisms have been proposed to manage collaborations in a specific industry. In the passenger airline industry, a problem receiving increased scholarly attention is that of how to share revenues among code-share partners. In addition to allocation of revenue, mechanisms must address the allocation of capacity among partners. Approaches to what is commonly called *alliance revenue management* can be classified broadly as static (those approaches in which capacity and pricing decisions do not change as capacity availability changes) or dynamic (approaches in which the mechanism adjusts recommendations according to the availability of seats in the flight network). An example of a static scheme is one in which revenue is shared between code-share partners according to a negotiated proportion (e.g., the proportion of miles that a customer flies on each airline). An example of a dynamic scheme is one which allocates revenue according to the bid prices of the partners, which change over time as inventory in the network diminishes.

Vinod [34] and Wright *et al.* [35] both address the problem of revenue management in passenger alliances. In general, Vinod asserts that the more the alliance can function as a single entity, the more benefit will be gained by collaborating. He acknowledges, however, that significant legal and technical challenges generally prevent full integration. Thus, analyzing an alliance among passenger airlines from a more decentralized perspective is necessary and he briefly explores the idea of how code-share partners can share revenue using a dynamic fare proration scheme based on bid prices. A key argument is that a revenue-sharing agreement should allocate to a carrier an amount of revenue for a flight leg that is at least as great as his bid price for that leg.

Wright *et al.* [35] conduct a more formal analysis of alliance revenue management mechanisms, analyzing each for its ability to induce alliance-optimal behavior. It is shown that static mechanisms can be appropriate in

limited situations, but in general a dynamic policy will lead to decisions that are more profitable for the alliance and its members. Furthermore, mechanisms that manage capacity according to a free-sale policy are promising. (A free-sale mechanism is one in which an airline purchases seats from a partner on an as-needed basis, as opposed to purchasing a block of seats to sell over time). The authors examine three types of free-sale dynamic mechanisms, and find the alliance characteristics that will make each type of scheme particularly successful.

Alliances among airlines also exist in the cargo segment of the industry. Houghtalen *et al.* [36] propose a mechanism for managing interactions among combination carriers, which are those carriers that transport cargo in the belly of passenger aircraft. The mechanism operates under assumptions similar to those applied in Agarwal and Ergun [15] and Gui and Ergun [16]: namely, that some form of centralized coordination or control is relied upon for the computation of mechanism parameters (i.e., capacity allotments and prices), but since carriers make their own routing decisions (and do so in a self-optimizing manner), a decentralized perspective is necessary when analyzing the computation and realization of revenue allocations. The mechanism proposed by the authors allocates capacity among partner carriers in a manner that ensures an alliance-optimal routing of cargo is feasible, then establishes prices for each flight leg that encourage carriers to make alliance-optimal routing decisions. The methodology for establishing prices, similar to that proposed by Agarwal and Ergun [15], is based on solving an inverse optimization problem. Computational experiments suggest that the proposed mechanism, when applied in a realistic alliance setting in which capacity prices must be fixed for a period of time, is not only very successful at achieving near-optimal alliance revenue, but also is very robust with respect to variability in cargo demand characteristics.

Because airline flights, even in an alliance setting, are operated by a single carrier, mechanisms designed to manage interactions among airlines can assume that every edge

in the transportation network is owned by a single carrier. In the liner shipping industry, in contrast, this assumption cannot be made. In an alliance in this industry, shipping companies work together to provide a specified (i.e., weekly) frequency of service on a given shipping route. As a result, a single edge in the transportation network may be serviced by multiple shipping companies. Agarwal and Ergun [5] study alliances in the liner shipping industry, from the perspective of how to allocate the costs associated with operating the shipping network. Their proposed mechanism utilizes a similar methodology as that employed in Agarwal and Ergun [15]. However, acknowledging that a core allocation is not guaranteed when there are multiple owners on an edge, constraints are introduced to ensure, at a minimum, rationality for subgroups of a given size. Computational experiments show that the mechanism is effective in finding capacity prices that lead to cost allocations in the core provided that the core is nonempty. The assignment of ships to the service routes in the network (which is accomplished before pricing decisions are made) can influence the costs assignments made by the mechanism but does not in general, impact the ability of the mechanism to find core allocations.

Exchange mechanisms among carriers in the truckload transportation industry are the focus of Özener *et al.* [37]. In contrast to the exchange mechanisms discussed above (related to the airline and liner shipping industry), the goal of this work is to identify beneficial ways for trucking carriers to exchange shipping lanes. That is, the carrier serving a particular edge (lane) in the network changes rather than carriers sharing capacity in a given lane. Lane exchanges can reduce carrier costs primarily by reducing costs associated with repositioning. Özener *et al.* [37] examine a decentralized setting in which carriers make decisions in a myopic manner; the only centralized perspective necessary is for determining the rules under which the exchange mechanism will operate. The authors propose four different mechanisms, where each mechanism is defined primarily by whether side payments and

information sharing are allowed among carriers. They find that while all four mechanisms are able to achieve substantial cost savings for the carriers, allowing information sharing has a greater impact on the cost savings achieved by the mechanism than allowing side payments between carriers.

An interesting related application of mechanisms designed to facilitate the exchange of resources is in the field of air traffic flow management. Specifically, the resources of interest are the landing (or arrival) slots at an airport, which are typically awarded to individual airlines based in part on the number of slots the airline has historically been allotted. In the case of a necessary reduction in the arrival capacity at an airport (typically due to weather), reassigning landing slots can benefit airlines by reducing the overall costs associated with a weather delay. The goal of slot trading mechanisms is to identify attractive exchanges of landing slots between carriers, typically with the aid of a mediator to evaluate bids or offers submitted by airlines. See, for example, Vossen and Ball [38] and Madas and Zografos [39]. Slot trading mechanisms differ from those discussed in detail above in that the resources being exchanged are not carrier-owned.

We return to the example introduced in the previous section to demonstrate the ideas underlying the exchange mechanisms discussed in this section. A mechanism designed to achieve maximum benefit from collaboration should facilitate the collaborative optimal solution in which loads $(1, 4, B)$ and $(2, 4, C)$ are delivered. Clearly, carrier A will need incentive to cooperate with this solution; one possibility is for carriers B and C to pay carrier A for the use of capacity. Thus the mechanism might determine that appropriate payments for capacity on edges $(1, 3)$ and $(2, 4)$ are 2.5 and 2.5, respectively, yielding a solution in which the net revenue associated with carrier A is 5, carrier B is 3.5, and carrier C is 0.5. Note that according to this solution, all carriers receive strictly positive benefit.

It is important to note that the design of the mechanism can have a substantial

impact on the benefit experienced by the participating carriers. For example, the solution proposed above is acceptable from the standpoint that all carriers receive strictly positive benefit from collaborating. However, there exists a range of possible payments that carriers B and C might offer to carrier A that fit this criteria. It is interesting to consider the fairness of various revenue allocations that might be obtained by a given mechanism. For example, one could argue that carrier A should receive more benefit, since it is contributing all of the valuable capacity in the network. On the other hand, carriers B and C are contributing the valuable cargo. Designing a mechanism in consideration of these issues is the subject of Houghtalen *et al.* [40].

Finally, we consider the possibility that a given solution may yield unintended results. Again, referring to the example above, consider a solution in which the cost associated with capacity on edge $(1, 3)$ is 5. That is, carrier B will have to pay carrier A a price of 5 for the use of that capacity. The cost of capacity on edge $(2, 4)$ is 2. If we examine this solution in detail, we find that it gives rise to a secondary market for capacity on edge $(2, 4)$. A capacity exchange in the secondary market will occur if carrier B realizes that a unit of capacity on edge $(2, 4)$ can be bought from carrier C for the price of 4, instead of buying capacity on $(1, 3)$ directly from carrier A for the price of 5. In this case, the resulting allocations actually realized by carriers A , B , and C will be 2, 2, and 4, respectively. This solution is unsatisfactory for carrier A , who could earn 4 by choosing to work alone instead of collaborating with carriers B and C .

AUCTION MECHANISMS

Collaborations among shippers and carriers in the truckload (TL) market aim to exploit the synergies among transportation requests. In a TL network, synergies arise from economies of scope rather than economies of scale [41]. More specifically, the complementarity of the transportation requests allows carriers to execute continuous moves, thereby reducing the need for

asset repositioning. One way to realize the cost savings affiliated with reduced asset repositioning is through transportation procurement auctions.

Transportation procurement auctions are widely used in practice. The auctions, conducted via an electronic marketplace, provide a mechanism for shippers to acquire transportation services from a large number of carriers. The US truckload transportation market is large and highly fragmented [5]. In this large and dynamic market, a fast and reliable auction mechanism is not only convenient but also may deliver significant cost savings as reported in Caplice and Sheffi [41], Moore *et al.* [42], Ledyard *et al.* [43], and Elmaghraby and Keskinocak [44]. TL procurement auctions are usually conducted as a reverse auction. In this setting, a single shipper (the auctioneer) announces the loads to be auctioned and the participating carriers (the bidders) submit their bids for the loads. Finally, the shipper evaluates the bids from the carriers and assigns his loads to the carriers. TL procurement auctions possess several desirable properties. Namely, they do not require information sharing among carriers, they can include additional business considerations such as the number of carriers utilized by a shipper, the capacities of carriers, and threshold volumes [41] and finally, they can be employed as a means for a secondary market among carriers [45].

Compared to other possible auction settings, a combinatorial auction is most suitable for exploiting economies of scope in transportation procurement since it allows carriers to bid for a set of transportation requests rather than bidding only for one load at a time. We refer the reader to De Vries and Vohra [46] and Abrache *et al.* [47] for a thorough review of combinatorial auctions and the associated issues in designing a combinatorial auction mechanism. In a combinatorial truckload procurement auction, the shipper announces the set of loads and invites a set of carriers to bid on these loads. If the shipper allows carriers to bid on all possible combination of the loads, the total number of bundles is equal to 2^n where n is the number of loads being auctioned. As mentioned in Sheffi [48], handling large instances

with a combinatorial auction mechanism is quite challenging: “Real problems, which may include thousands of lanes, dozens or hundreds of carriers, and millions of combination bids, are more challenging and require special code.” To overcome this issue, the shipper may impose a restriction on the number of bundles for which a carrier may submit a bid. For example, the shipper may use a pre-specified bidding language [49]. By designing a bidding language in a certain way, the shipper can influence the carriers to submit bids on a limited number of bundles [50]. However, imposing a very strict restriction on the number of bundles decreases the possibility of exploiting the synergies and hence limits the effectiveness of the combinatorial auction. Clearly, there is a delicate trade-off between the efficiency and implementability of the auction mechanism.

After the shipper auctions the loads, the carriers (who may have preexisting commitments to other loads) decide on the bid prices for the bundles of loads. A carrier’s bid calculation process requires a precise estimation of the marginal cost of each bundle of loads. That is, a carrier has to solve an optimization problem to determine the least cost set of tours to serve its preexisting load commitments plus the bundle of loads in consideration and compute the associated bid. The carriers have to carry out this process for every bundle they anticipate acquiring, unless an implicit bidding approach is employed as described in Chen *et al.* [51] and Beil *et al.* [52]. When the underlying optimization problem is NP-hard, this bid selection process significantly limits the implementation of such auction mechanisms for practical purposes. Using approximation algorithms for the bid selection process of the carriers may improve the computational efficiency, however, this approach will produce suboptimal solutions for the carriers [53,54]. Furthermore, even if the underlying optimization problem is polynomially solvable, the bid determination process may take an exponential effort if no limit is imposed on the number of bundles for which a carrier can submit a bid.

Even if we assume that the carriers can exactly determine the marginal cost of serving a bundle of loads, they are not required to submit this value as a bid to the shippers. Depending on the incentives in a collaborative and competitive environment, the selfish carriers rarely disclose their private information and may lie about their costs to achieve higher benefits. Even in environments where there is a centralized decision maker, the trust issues between participants often threaten the collaboration and hence there is always an inherent risk of losing collaborative opportunities. However, there exist certain auction mechanisms that prevent carriers from lying about their cost information. In Vickery, or second-bid-price auctions, the carriers are guaranteed to bid their true cost value for the bundles of loads. In a single item Vickery auction, the carriers submit their bids to the shipper for the item and the item is awarded to the carrier with the lowest bid. However, instead of being paid the amount of the lowest bid, the winning carrier is paid the amount of the second-lowest bid. In the combinatorial auction extension, a winning carrier is paid its total combined bid for the awarded bundles plus an additional payment. This additional payment is calculated by excluding the particular carrier from the auction, recalculating the total cost of the auction to the shipper, and then subtracting the original cost of the auction (including the particular carrier) to the shipper. We refer to Figliozzi *et al.* [55] and Beil *et al.* [52] for discussions of the implementation of Vickery auctions in transportation procurement markets. In most other auction settings, such as first-bid-price auction, the truthfulness of the carriers is not guaranteed (as in Song and Regan [56] and Chen *et al.* [51]).

After multiple carriers submit their bids on the bundles of loads to the shipper, the shipper solves a winner determination problem to assign bundles to the carriers. The objective of the shipper is to determine the minimum cost allocation of the lanes to the bidding carriers, thereby minimizing the total transportation cost. However, as the bids from various carriers may include bids for overlapping sets of lanes, solving the winner determination problem requires

the solution of a set partitioning-type problem, which is known to be *NP-hard* [46]. Restricting the number of bundles on which a carrier is allowed to bid can reduce the size of the winner determination problem, and employing approximation heuristics for solving the set partitioning problem can further mitigate the complexity of the problem. However, both actions will significantly decrease the effectiveness of the auction mechanism in exploiting the synergies among transportation requests.

We return to the example introduced in the section titled “Centralized Collaboration Mechanisms” to demonstrate how auction mechanisms work in this context. To this end, we slightly modify the example so that the capacity on all four edges is equal to one. Furthermore, they are no longer operated by carrier A. The origin, destination, per-unit revenue, and size of each load is as described in Table 1. In this auction setting, the carriers bid on available capacity on the edges and the winner is determined by solving a winner determination problem (if necessary). If we assume a single item auction setting where each edge is auctioned sequentially, the resulting bids from the carriers are given in Table 2. Note that carrier B does not submit any bids because it cannot generate any revenue by acquiring capacity only on a single edge. The winning bids are carrier A’s bid of 2 for edge (1,3) and carrier C’s bid of 3 for edge (2,4), which generates a total revenue of 5. This example clearly shows that single item auction setting ignores the synergies between auctioned items.

Next, we consider a combinatorial auction setting for this example. Even for this small instance with only three carriers and four “items” on which carriers are bidding, each carrier has to submit a bid for 15 different bundles (if no bid limit is imposed), and the resulting winner determination problem has 45 different bids. In the optimal solution, the winning bids are carrier B’s bid of 6 for edges (1,3) and (3,4) and carrier C’s bid of 3 for edge (2,4), which generates a total revenue of 9. This corresponds to the centralized optimal solution for this instance. Note that if

Table 2. Carrier Bids in Sequential Single Item Auction

Edge	Carrier A	Carrier B	Carrier C
(1,2)	0	0	0
(1,3)	2	0	0
(2,4)	2	0	3
(3,4)	0	0	0

we limit the number of bids from each carrier in order to increase the computational efficiency, we may not achieve the system optimal solution.

CONCLUSIONS AND FUTURE RESEARCH DIRECTIONS

In this article, we have described three generic mechanisms that allow for collaboration in the transportation industry. Each of these mechanisms requires different levels of coordination and information sharing among the participating entities while yielding different levels of efficiency. One important conclusion we derive is the fact that a fair and efficient mechanism with limited coordination requirements can be designed using analytical tools that properly take into account economies of scope and scale.

Future research directions include (i) the further study of the mathematical structures of these mechanisms to identify the best possible payoffs and how to achieve them computationally; (ii) understanding the implementation and fairness requirements in different industries and then improving the mechanisms by incorporating these additional constraints; and (iii) understanding how the discussed mechanisms perform under uncertainty and the design of robust mechanisms.

Shortest path problems (SPPs) play a central role in the field of network flows. They arise frequently in a wide variety of applications either as a stand-alone problem or as a part of more complex problem settings, thereby attracting the attention of practitioners as well as researchers. Several applications and variants of the problem have been discussed in earlier articles. SPPs typically involve a network represented as a directed graph $G = (N, A)$, where N is the set of n nodes and A denotes the set of m arcs between nodes. In a single-source shortest path problem (SSPP), the network contains a distinguished node s , called the *source node*, and each arc $(i, j) \in A$ has an associated weight (cost) w_{ij} , also referred to as the length of the arc. The length of a directed path is defined as the sum of the length of all constituent arcs. The SSPP is used to determine the directed path of the shortest length, from the source node to all other nodes (Fig. 1). In all-pairs shortest path problems (ASPPs), we determine the shortest paths between each pair of nodes. The SPP can also be viewed as a special case of the *minimum cost flow problem* [1], where one unit of flow is to be sent from the source node to all other nodes in an incapacitated network at the minimum cost possible. In this article, we make several assumptions about the network, which are not restrictive in practice and can be

easily relaxed if required. The last assumption is restrictive but all algorithms described in this article terminate after detecting the presence of a negative cycle.

- *Data Integrality.* This is necessary for those algorithms whose complexity depends on data (maximum arc length, C). If required, we can convert a rational arc length into an integer value by multiplying it with a suitably large number.
- *Directed Path from Source Node s to Every Other Node.* If there does not exist a path from s to a node i , we can add an arc (s, i) of a very large length to satisfy this assumption. For an ASPP, the graph is assumed to be strongly connected; this assumption can be satisfied by adding arcs of infinite length between the unconnected nodes.
- *Directed Network.* A network with undirected arcs and nonnegative arc lengths can be easily converted into a directed network by replacing each undirected arc $\{i, j\}$ with two directed arcs, (i, j) and (j, i) , of the same length w_{ij} . It should be observed that an undirected arc with negative length constitutes a negative cycle.
- *No Negative Cycle.* We assume that the network does not contain a directed cycle of negative length. The decision version of the SPP on graphs with negative cycles is NP-complete, and no polynomial time algorithm exists unless $P = NP$. Existing algorithms for the SPP identify shortest walks that happen to be shortest paths when no negative cycles are present, which is not true for general networks. In the presence of negative cycles, one can drive shortest walk lengths to minus infinity by traversing a reachable negative cycle infinitely many times while shortest path lengths are always lower bounded by $-nC$.

Figure 1. Illustration of a shortest path tree.

Before discussing the details of the algorithms, we briefly review the data structures used to store a shortest path from the source to all other nodes. A naive approach would be to store it in an array of size on the order of $O(n^2)$, as each path may contain at most $n - 1$ arcs. However, with the development of new data structures, such as shortest path tree, it is possible to store it in an array of size $n - 1$. In a shortest path tree, the distance between the selected root node and all other nodes is minimal. It is encoded by storing a predecessor pointer $\text{pred}[j]$ for each node j other than s . Figures 1(b) (c) show two examples of shortest path trees (highlighted arcs) for the network given in Fig. 1(a). It is based on the following property of shortest paths:

Property 1. If the path $P = i_1, i_2, \dots, i_k$ is a shortest path from node i_1 to i_k , then for every $h = 2, 3, \dots, k - 1$, the subpath $P' = i_1, i_2, \dots, i_h$ is the shortest path from i_1 to i_h .

The scope of SPPs differs on the basis of the individual scenario. We discuss five classes of SPP in this article: (i) Shortest paths in acyclic networks; (ii) SSPP with nonnegative arc lengths; (iii) SSPP with general arc lengths; (iv) ASPP with nonnegative arc lengths; and (v) ASPP with general arc lengths. The single destination SPP, which is another variant of the problem, aims to determine the shortest path length from each node to a common destination. It can be converted to the SSPP simply by reversing the direction of the arcs.

In this article, each algorithm for SSPP that we discuss maintains a distance label

$d(i)$ for each node $i \in N$ of the network during its execution. At any intermediate step these labels represent the upper bounds on the shortest paths from the source to node i . At termination, these denote the optimal shortest path lengths. We can now extend Property 1 to achieve the optimality conditions for SSPP.

Theorem 1. For every node $i \in N/\{s\}$, let $d(i)$ denote the distance label at optimality, that is, vector $\mathbf{d}$ denotes the shortest path distance with $d(s) = 0$. Then, a directed path P from the source node to node j is a shortest path if, and only if, $d(j) \leq d(i) + w_{ij} \forall (i, j) \in A$, and $d(j) = d(i) + w_{ij} \forall (i, j) \in P$.

Let us define the reduced arc length w_{ij}^d of an arc $(i, j) \in A$ with respect to the distance labels as $w_{ij}^d = w_{ij} + d(i) - d(j)$. We mention the following properties, which will be useful in algorithmic developments.

Property 2.

- For any directed cycle W , $\sum_{(i,j) \in W} w_{ij}^d = \sum_{(i,j) \in W} w_{ij}$.
- For any directed path P from node k to node l , $\sum_{(i,j) \in P} w_{ij}^d = \sum_{(i,j) \in P} w_{ij} + d(k) - d(l)$.
- If vector $\mathbf{d}$ represents the shortest path distances, $w_{ij}^d \geq 0 \forall (i, j) \in A$.

SHORTEST PATHS IN ACYCLIC NETWORKS

A network is said to be acyclic if it does not contain a directed cycle. We order the nodes

of this network so that $i < j$ for each arc $(i, j) \in A$. This ordering of nodes is called *topological ordering* and can be easily determined by traversing all arcs in $O(m)$ time. It can be observed that we need to conveniently access all arcs emanating from each node $i \in N$, and to facilitate that we maintain an adjacency list $A(i)$ of node i . We now present a simple *reaching algorithm* to find a shortest path in an acyclic network using the topological order and the adjacency list:

Step 1. Initialize $d(s) = 0$ and $d(i) = \infty$, $\forall i \in N/\{s\}$.

Step 2. Examine each node in topological order i and scan arcs in $A(i)$. If for any arc $(i, j) \in A$, $d(j) > d(i) + w_{ij}$, set $d(j) = d(i) + w_{ij}$ and $\text{pred}[j] = i$.

The algorithm is illustrated clearly in Fig. 2. The network in Fig. 2(a) is first topologically ordered as shown in Fig. 2(b). Thereafter, we apply the reaching algorithm by considering each node in topological order. The dotted arcs emanate from the node under examination, while the bold arcs represent the partial paths which are included in the final shortest path. As given in Step 1, we

Figure 2. Illustrating the reaching algorithm for the shortest path in an acyclic network.

initialize the distance labels of the source to zero and that of all other nodes to infinity (Fig. 2(b)). Figure 2(c) through (f) examines each node one at a time and updates the distance labels of adjacent nodes. The final shortest path is shown in Fig. 2(g).

The correctness of the reaching algorithm follows from the observation that whenever a node is examined its distance label is optimal. We refer readers to Ahuja *et al.* [2] for the detailed proof. The algorithm solves the problem in $O(m)$ time, as it traverses each arc only once and spends $O(1)$ time on it. We should also note that this is the best possible complexity because any algorithm must examine each arc of the network.

Though the algorithm described above is very simple and effective, it cannot be applied in general cases that contain cycles. However, we utilize the same basic strategy and optimality conditions with some additional steps to solve more complex cases. The next class of problem is the SSPP with nonnegative arc lengths.

SINGLE-SOURCE SHORTEST PATHS WITH NONNEGATIVE ARC LENGTHS

A classical approach to solve the SSPP in a network with nonnegative arc lengths was first proposed by Dijkstra in 1959. At each step, Dijkstra's algorithm maintains a distance label $d(i)$ for each node $i \in N$ and designates it as either temporary or permanent. The distance label corresponding to the

permanent node represents a shortest path from the source, while that corresponding to the temporary node gives an upper bound on the shortest path distance from the source. We start by initiating the distance label of source node to zero and making it permanent. The distance labels of all other nodes are initialized to infinity. The basic idea is the same as in the reaching algorithm. We start from the source s , then examine each node one at a time updating the distance labels of its adjacent nodes. The only difference is that in each iteration of Dijkstra's algorithm the node with the lowest distance label is examined, while in the reaching algorithm it is chosen in topological order. The chosen node is made permanent because none of the arcs from a temporary node can reduce its distance label further due to the nonnegative arc length restriction. The operation of selecting a node with the shortest distance label is referred to as *node selection*; the operation of subsequently updating the distance labels is referred to as *distance update* or *relaxing*.

Dijkstra's algorithm maintains an outwardly directed tree T rooted at the source node that spans all nodes with finite distance labels. Every tree arc, (i, j) , satisfies the property $d(j) = d(i) + w_{ij}$ with respect to the current distance label. The arc (i, j) indicates that, in the current shortest path from source to node j , node i precedes node j . At the termination, the tree becomes the shortest path tree. Figure 3 gives the algorithmic framework of Dijkstra's algorithm. Let N_P and N_T

```

algorithm Dijkstra;
begin
   $N_P := \emptyset; N_T := N;$ 
   $d(i) := \infty \forall i \in N;$ 
   $d(s) := 0$  and  $\text{pred}(s) := 0;$ 
  while  $|S| < n$  do
    begin
      find  $i$  such that  $d(i) = \min\{d(j) : j \in N_T\};$  //Node-Selection();
       $N_P := N_P \cup \{i\};$ 
       $N_T := N_T - \{i\};$ 
      for each  $(i, j) \in A(i)$  do //Relaxing
        if  $d(j) > d(i) + w_{ij}$  then  $d(j) := d(i) + w_{ij}$  and  $\text{pred}(j) := i;$ 
    end;
  end;

```

Figure 3. Framework of Dijkstra's algorithm.

Figure 4. Illustrating Dijkstra's algorithm.

denote the permanent and temporary nodes respectively.

We illustrate Dijkstra's algorithm in Fig. 4 using the network given in Fig. 1(a). The gray nodes are permanent, while the white ones are temporary. The dotted arcs represent the arcs being examined in a particular iteration. As shown in Fig. 4(a), we initialize the distance labels of source to zero and all other nodes to infinity. Thereafter, we examine the source node in Fig. 4(b), and reduce the distance labels of node 2 and node 3 to 3 and 5, respectively. As node 2 has the lowest distance label, it is made permanent and the arcs emanating from it are examined next. The process continues as shown in Fig. 4(b) through (e), terminating with the shortest path as shown in Fig. 4(f).

The correctness of Dijkstra's algorithm can be established by showing that at each stage two properties are always maintained: (i) for each node $i \in N$, $d(i)$ is the shortest path from s to i among all paths that pass through nodes only in N_P , and (ii) for each $i \in N_P$, $j \in N_T$, $d(i) \leq d(j)$. The details

of the proof can be seen in Ref. 2. The worst-case complexity of the algorithm is governed by two main operations: (i) *Node selection*: The algorithm selects one node from the set of temporary nodes whose cardinality decreases by 1 in each iteration. Hence, the overall running time for this operation is $n + (n-1) + \dots + 1 = O(n^2)$. And, (ii) *Relaxing/distance-update*: Each arc is relaxed once, thereby adding $O(m)$ to the total running time. This complexity is based on simple data structures and is appropriate for very dense networks. Researchers have attempted several implementation approaches, and have successfully improved either the worst-case complexity or the running time in practice. We list all of these implementations in Table 1.

The applicability of Dijkstra's algorithm is limited to networks with all nonnegative length arcs. It selects the node with the lowest distance label from the set of temporary nodes and makes it permanent, based on the fact that no temporary node can reduce it any further. This may not be true if a negative arc

Table 1. Running Time of Dijkstra's Algorithm with Various Data Structures

Algorithm	Running Time

is incident to it from a temporary node. In the next section we discuss several approaches to solve the problem with general arc lengths.

SINGLE-SOURCE SHORTEST PATHS WITH GENERAL ARC LENGTHS

The presence of negative arc weights makes the problem more complex and renders the previous incremental algorithm inapplicable. It should be noted that the presence of negative arcs does not signify the presence of a negative cycle, which would make the problem NP-hard. Therefore, the algorithms in this case should either find a shortest path or terminate with the identification of a negative cycle.

Generic Label-Correcting Algorithm

The shortest path algorithms are generally divided into two groups: *label setting* and *label correcting*. Both approaches iteratively assign distance labels to nodes, but vary in labeling them either permanent or temporary. The label-setting algorithms designate

one node permanent at each iteration, while the label-correcting algorithms consider all nodes temporary until the final iteration. The label-setting algorithm is an incremental algorithm and, therefore, is applicable to only acyclic networks or networks with non-negative arc weights. Dijkstra's algorithm discussed in the section titled "Single-Source Shortest Paths with Nonnegative Arc Lengths" belongs to this class. On the other hand, the label-correcting algorithm continues checking all arcs repeatedly until no improvement is possible. Accordingly, it is applicable to all networks that include general arc lengths but no negative cycle.

The generic label-correcting algorithm, similar to Dijkstra's algorithm, maintains a distance label for every node and its predecessor at each stage. The predecessor index of a node j , $\text{pred}(j)$, represents the node prior to node j in the current shortest path of length $d(j)$. At the termination point, the graph formed by these indices is a shortest path tree if no negative cycle is encountered. The basic concept is to successively update the distance labels of each node until they satisfy the optimality conditions given by Theorem 1. We show the algorithmic framework in Fig. 5.

With Property 2 at optimality, the distance labels must satisfy the nonnegative condition on reduced arc lengths, that is, $w_{ij}^d \geq 0 \forall (i, j) \in A$. The generic label-correcting algorithm selects an arc (i, j) that violates this condition, and decreases the distance label of node j , thereby making its reduced length equal to zero. We illustrate this on the network shown in Fig. 6(a), and have added negative arcs to make it more general. If the algorithm selects the arcs (1, 2), (1, 3), (2, 5), (3, 4), (4, 2), and (2, 5) in this sequence, we obtain the distance labels

Figure 5. Framework of generic label-correcting algorithm.

   $d(s) := 0$  and  $\text{pred}(s) := 0$ ;
   $d(i) := \infty \forall i \in N - \{s\}$ ;
  while there exists an arc so that  $d(j) > d(i) + w_{ij}$  do
     $d(j) := d(i) + w_{ij}$  and  $\text{pred}(j) := i$ ;
  end;
end;

```

Figure 6. Illustrating the generic label-correcting algorithm.

shown in Fig. 6(b) through (g). At this point, no arc violates its optimality condition and the algorithm terminates with the shortest path tree as shown in Fig. 6(h). Please note that all nodes are temporary until the last iteration, after which all of them simultaneously become permanent.

The correctness of the algorithm follows from the fact that at its termination all conditions of Property 2 are satisfied. We briefly look at the complexity in a special

case where all data are integral. Let C be the longest arc length. It can be observed that any distance label is bounded within the range $[nC, -nC]$, as a path can contain at most $(n - 1)$ arcs of length C . Therefore, any distance label can be updated at most $2nC$ times as each update decreases it by at least one unit because all data are integers. It may also take $O(m)$ time to find the arc violating the optimality condition. Consequently, the total number of updates for all

nodes is at most $2n^2C$, which takes $O(n^2mC)$ time. Without going into detail, we state that in a network with irrational arc lengths the worst-case complexity of the generic label-correcting algorithm is $O(2^n)$ time [2].

The generic label-correcting algorithm does not specify a method for selecting an arc violating Property 2. Therefore, an inefficient approach may require a very high running time. Bellman (1957) and Ford (1956) proposed a method that makes this phase very efficient. We discuss it in the following section.

Bellman–Ford Algorithm

As discussed earlier, the Bellman–Ford algorithm solves the SSPP with general arc lengths but fails if, and only if, the network contains a negative cycle reachable from the source. It either calculates the shortest paths or reports the presence of a negative cycle. We discuss the details about the negative cycle detection later in this section. The algorithm uses the ideas of dynamic programming. Similar to the generic label-correcting algorithm, the Bellman–Ford algorithm maintains the distance labels and predecessor indices of all nodes at each stage. Dijkstra’s algorithm follows an incremental approach for distance updates, considering the arcs emanating only from a set of nodes specifically chosen. Conversely, in the Bellman–Ford algorithm, all arcs are examined and the distance labels violating the optimality conditions are updated. The algorithmic framework is given in Fig. 7.

We illustrate the Bellman–Ford algorithm in Fig. 8 using the numerical example

given in Fig. 6(a). As stated in the algorithm, we initialize the distance label of source to zero and all other nodes to infinity, as shown in Fig. 8(b). In each iteration, we check all arcs violating the optimality conditions and update the distance labels as well as the predecessor indices. In Fig. 8(b), only the arcs emanating from the source are violating the optimality conditions. Therefore, the distance labels of nodes 2 and 3 are reduced from infinity to 3 and 5 respectively. In the next three iterations [Figs 8(c) through (e)], all arcs are scanned repetitively. Finally, we determine the shortest path tree using the predecessor indices as shown in Fig. 8(f). As discussed earlier, none of the nodes are permanent until the last iteration, after which all of them become permanent simultaneously.

We next show that the Bellman–Ford algorithm performs at most $n - 1$ passes (first *for-loop* in Fig. 7) to achieve the optimal distance labels. It can be observed that in each pass all arcs are scanned, taking a total of $O(m)$ time. Therefore, the running time of the algorithm is $O(nm)$. We first show by induction that at the end of the k th pass, the algorithm computes the shortest path distances for all nodes that are connected to the source node by the shortest path consisting of k or fewer arcs. This is true for $k = 1$. Now, suppose that the assertion is true for the k th pass and $d_k(j)$ is the distance label at the k th pass. By definition, $d_k(j)$ is the shortest path from source to node j , provided that a shortest path to it contains k or fewer arcs and otherwise is an upper bound on the shortest path length. Consider a shortest path $s = i_0 - i_1 - i_2 - \dots - i_k - i_{k+1} = j$ from source s

```

algorithm Bellman–Ford;
begin
     $d(s) := 0$  and  $\text{pred}(s) := 0$ ;
     $d(i) := \infty \forall i \in N - \{s\}$ ;
    for each  $k := 1$  to  $n - 1$  do
        for each  $(i, j) \in A$  do //Relaxing
            if  $d(j) > d(i) + w_{ij}$  then  $d(j) := d(i) + w_{ij}$  and  $\text{pred}(j) := i$ ;
        for each  $(i, j) \in A$  do
            if  $d(j) > d(i) + w_{ij}$  then "Network contains negative cycle";
    end;

```

Figure 7. Framework of Bellman–Ford algorithm.

Figure 8. Illustrating Bellman–Ford algorithm.

to node j consisting of $k+1$ arcs, but no shortest path containing fewer than $k+1$ arcs. By Property 1, the path $i_0 - i_1 - i_2 - \dots - i_k$ is a shortest path from source to node i_k ; by induction hypothesis, the distance label of node i_k at the end of the k th pass must be equal to the length of this path. Therefore, in the $k+1$ th pass, we examine the arc (i_k, i_{k+1}) and set the distance label of i_{k+1} equal to the length of the path $i_0 - i_1 - i_2 - \dots - i_k - i_{k+1}$. It establishes our claim and also proves the correctness of the algorithm that, if we set $k = n - 1$ as a path, it can contain at most $n - 1$ arcs.

If a network contains a negative cycle, it can be easily detected by the Bellman–Ford algorithm as shown in the second “for-loop” of Fig. 7. As discussed earlier, each distance label must be at its optimal value after $n - 1$ iterations; therefore, additional distance label updates indicate the presence of a negative cycle. The worst-case complexity of the Bellman–Ford algorithm as shown above is $O(mn)$, as all arcs are examined

in each pass. It can be improved for practical purposes by storing the nodes in a list whose distance labels change in a pass, and then examining the list in a first-in-first-out (FIFO) order in the next pass. We refer readers to Ref. 2 for the details of the FIFO-based algorithm. We now extend the scope of our problem from single-source shortest path to ASPPs.

ALL-PAIRS SHORTEST PATH PROBLEMS

In this section, we consider the problem of finding the shortest path distances between all pairs of nodes in a network. It can be viewed as an extension of SSPP, and any algorithm described earlier can be modified to solve the ASPP. We suggest two approaches for solving this problem: (i) repetitive single-source shortest path algorithms and (ii) Floyd–Warshall’s algorithm. As stated earlier, we assume that the network is strongly connected and that it does not contain a negative cycle. However,

if negative cycles are present, all of these algorithms terminate after their detection.

Repetitive Single-Source Shortest Path Algorithm

We can solve the ASPP by running a single-source shortest path algorithm n times, once for each node as a source. If all arc lengths are nonnegative, we can use any SSPP algorithm, such as Dijkstra's algorithm, taking $f(n, m, C)$ time. Therefore, the total running time of this algorithm is $O(nf(n, m, C))$. However, if the network contains some negative arcs, we can either apply the Bellman–Ford algorithm n times taking $O(n^2m)$ time or apply any algorithm after transforming the network to one with nonnegative arc lengths as discussed next.

We select a node s and apply the Bellman–Ford algorithm to compute the shortest path distances from source to all other nodes. If a negative cycle is detected, the all-pairs shortest path also contains a negative cycle; otherwise, the shortest distance labels denote the shortest path from node s . Now, we replace the current arc lengths with the reduced arc length; that is, $w_{ij}^d = w_{ij} + d(i) - d(j)$ for each arc $(i, j) \in A$. As explained in the introductory section, since the reduced arc lengths are always positive, we can now apply any SSPP algorithm. Once the algorithm terminates, the actual shortest path distance between each pair of nodes, (k, l) , can be determined by adding $d(l) - d(k)$ to the corresponding shortest path distance in the modified network. We differentiate the distance label obtained from each source by maintaining two indices: first for the source and second for the destination. In other words, for each pair of nodes (k, l) , we maintain the distance label $d[k, l]$, which represents an upper bound on the shortest path length from k to l . This method requires $O(nm)$ time for one application of the Bellman–Ford algorithm, and $O(nf(n, m, C))$ time for solving n shortest paths problems with a different source. Therefore, the total running time equals $O(nm + nf(n, m, C)) = O(nf(n, m, C))$. For example, the running time with the Fibonacci heap implementation of Dijkstra's algorithm is $O(mn + n^2 \log n)$.

Floyd–Warshall Algorithm

The Floyd–Warshall algorithm uses the dynamic programming approach to solve the all-pairs SPPs. Let $d_k[i, j]$ represent the shortest path length from node i to node j using only the nodes $1, 2, \dots, k-1$ as the internal nodes. The algorithm repetitively computes $d_1[i, j]$, $d_2[i, j]$, and so on, until $d_{n+1}[i, j]$ for all pairs (i, j) of nodes. It is clear that $d_{n+1}[i, j]$ represents the optimal shortest path lengths, as any node can be the internal node. Therefore, the recursive relation, which is the core of any dynamic programming approach, is given by

$$d_k[i, j] = \begin{cases} w_{ij} & \text{if } k = 0 \\ \min(d_{k-1}[i, j], d_k[k, j] + d_k[k, j]) & \text{if } k \geq 1. \end{cases}$$

The relation at $k = 0$ is obvious as we do not include any internal nodes. A shortest path that uses only nodes $1, 2, \dots, k$ either does not pass through node k , in which case $d_{k-1}[i, j]$ is minimum, or it does, in which case $d_k[i, k] + d_k[k, j]$ is minimum. It also maintains the predecessor indices $\text{pred}[i, j]$, for each node pair, which denotes the last node prior to node j in the current shortest path from node i to node j . This helps in building shortest path trees for each source node. The formal description of the algorithm is given in Fig. 9.

```

algorithm Floyd–Warshall;
begin
     $d[i, j] := \infty$  and  $\text{pred}[i, j] := 0; \forall [i, j] \in N \times N;$ 
     $d[i, j] := 0 \forall i \in N;$ 
    for each arc  $(i, j) \in A$  do
         $d[i, j] := w_{ij};$  and  $\text{pred}[i, j] := i;$ 
    for each  $k := 1$  to  $n$  do
        for each  $[i, j] \in N \times N$  do
            if  $d[i, j] > d[i, k] + d[k, j]$  then
                begin
                     $d[i, j] := d[i, k] + d[k, j];$ 
                     $\text{pred}[i, j] := \text{pred}[k, j];$ 
                end;
    end;

```

Figure 9. Framework of the Floyd–Warshall's algorithm.

Figure 10. Illustrating the Floyd-Warshall's algorithm.

It is clear from Fig. 9 that the Floyd–Warshall's algorithm performs n passes, increasing the number of possible internal nodes in each successive pass. Each pass examines and updates the distance label of every pair of nodes requiring $O(n^2)$ time. Therefore, the total time required for the algorithm is $O(n^3)$. We explain it further using a numerical example given in Fig. 10(a), a general graph with negative length arcs but with no negative cycle. We present $d_k[i, j]$ (shaded matrix) and $\text{pred}_k[i, j]$

(plain matrix) matrices for all $[i, j] \in N \times N$ at each (k) of the $n = 5$ passes. In Fig. 10(b), $d_1[i, j]$ and $\text{pred}_1[i, j]$ (the distance label and predecessor of node j in the current path from node i) for each pair (i, j) of nodes are given when no internal node is allowed in the path. It can be observed that each value in the first distance matrix corresponds to the length of an arc. In Fig. 10(c), we allow only node 1 as the internal node in the paths. Therefore, the shortest path length from node 4 to node 2 reduces to 3 and, from node

4 to node 5, it reduces to -2 . In the next four passes Fig. 10(d)–10(g), we successively allow nodes 2, 3, 4, and 5 to be considered as the internal nodes of the paths. Finally, we achieve all-pairs shortest path distances in Fig. 10(g). We use the predecessor matrix to trace the shortest paths between each pair of nodes. For example, the shortest path between node pair (1, 2) can be traced as 1-5-4-3-2 and its total weight is 1.

As discussed earlier, the presence of a negative cycle makes the problem NP-hard. In that case, the Floyd–Warshall algorithm terminates with the negative cycle detection in $O(n^3)$ time. We incorporate two tests at each distance label update: (i) if $i = j$, check whether $d[i, i] < 0$; and (ii) if $i \neq j$, check whether $d[i, j] < -nC$. If either of these two tests returns true, the network contains a negative cycle.

Though the Floyd–Warshall’s algorithm is very efficient, several researchers have attempted to develop algorithms with an improved worst-case and average-time complexity. We list some recent developments in the single-source shortest path in Table 2 and in the all-pairs shortest path in Table 3. It should be noted that with new advances in the computational fields, the complexity of algorithms also changes.

SUMMARY

SPPs are one of the most fundamental computational problems, both from theoretical and practical perspectives. In this article, we

Zwick [25]	$O(n^{2.575} C^{0.681})$

^a $\alpha(m, n)$, inverse Ackermann’s function.

have studied several variants of the problem, each with special characteristics: (i) shortest paths in a directed acyclic network; (ii) single-source shortest paths with nonnegative arcs; (iii) single-source shortest paths with general arcs; (iv) all-pairs shortest paths with nonnegative arcs; and (v) all-pairs shortest paths with general arcs. We start with the most restrictive class of the problem (i) and gradually evolve toward the most general version (v). We have discussed widely studied algorithms for each variant of the problems. All of these algorithms are iterative and rely on the same basic concept: distance labels (upper bound on the shortest paths). They also maintain predecessor indices for all nodes to construct the shortest path trees. Finally, we provide a brief overview of the recent advances in SPPs.

SIMPLEX-BASED LP SOLVERS

ISTVÁN MAROS

Department of Computing, Imperial
College London, London, UK

Department of Computer Science and
Systems Technology, University
of Pannonia, Veszprém, Hungary

Two main algorithms are used to solve linear programming (LP) problems, namely, the simplex method (SM) and the interior point methods. As both are needed in practice (not discussed here), their development has been a great challenge which initiated substantial research activities. Nowadays, proper implementations of both types of solvers are very capable and can solve large-scale LP problems reliably and efficiently. This article concentrates on the computational techniques of the SM, and discusses the structure and algorithmic components of state-of-the-art simplex-based solvers. The reader is assumed to be familiar with the theory of the SM.

SUMMARY OF THE REVISED SIMPLEX METHOD

The SM has two main versions. They are the primal and the dual SMs. The usefulness of both necessitates the inclusion of them in the toolbox of an advanced optimization system.

Modern implementations of the SM still follow the principles and logic of the original version introduced by Dantzig [1]. However, every algorithmic component has undergone a serious revision and the newly developed advanced techniques are very sophisticated and efficient.

The key to solving large-scale LP problems is the use of the *revised simplex method* (RSM) and exploiting sparsity of the emerging matrices (and vectors). It is well known that the RSM keeps the matrix of constraints in original (sparse) form. In early implementations, the simplex operations

were performed using the *product form of the inverse* (PFI) of the basis [2]. Later the LU decomposition for LP (first suggested by Markowitz [3]) proved to be superior and is used nearly exclusively in commercial and academic solvers.

To be able to discuss the advanced simplex techniques, the problem to be solved and the algorithmic steps of the RSM have to be reviewed.

The problem considered is supposed to be in a computational form:

$$\begin{array}{ll} \min & z = \mathbf{c}^T \mathbf{x}, \\ \text{s.t.} & \mathbf{A}\mathbf{x} = \mathbf{b}, \\ & \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}, \end{array} \quad (1)$$

where $\mathbf{A} \in \mathbb{R}^{m \times n}$, $\mathbf{c}, \mathbf{x}, \mathbf{l}, \mathbf{u} \in \mathbb{R}^n$, and $\mathbf{b} \in \mathbb{R}^m$. Some components of $\mathbf{l}$ and $\mathbf{u}$ can be $-\infty$ or $+\infty$, respectively. $\mathbf{A}$ contains a unit matrix $\mathbf{I}$ corresponding to the added *logical variables* that make every constraint an equality. Therefore, $\mathbf{A} = [\mathbf{I}, \bar{\mathbf{A}}]$ which implies $\text{rank}(\mathbf{A}) = m$. The original variables of the problem (that multiply the columns of $\bar{\mathbf{A}}$) are called *structural variables*.

This problem can be solved by the primal- or the dual SM. Using any of them provides solution to both the primal and dual *problems*. It is useful to emphasize that both algorithms work on problem (1) (which can be called *primal problem*) but under different assumption and use different rules for the iterations.

The *main algorithmic steps* of an iteration of the primal (dual) SM are summarized below.

Assume a primal (dual) feasible basis $\mathbf{B}$ is given. Matrix $\mathbf{A}$ is logically partitioned as $\mathbf{A} = [\mathbf{B} \ \mathbf{R}]$, where $\mathbf{B}$ contains the basic columns and $\mathbf{R}$ the rest.

1. *Pricing*. Check if the current basis is optimal. If yes, algorithm terminates. Otherwise, select an incoming (dual: outgoing) variable x_q (dual: x_{Bp} , the p th basic variable).

2. *Transform Candidate Column (Row).* Determine the updated form of column q , $\alpha_q = \mathbf{B}^{-1}\mathbf{a}_q$ (dual: nonbasic part of row p , $\rho^p = \mathbf{e}_p^T \mathbf{B}^{-1}\mathbf{R}$).
3. *Ratio Test.* Perform primal (dual) ratio test with eligible positions and determine the primal (dual) steplength. If it is $\mp\infty$ the solution is unbounded, algorithm terminates.
4. *Updating.* Perform transformations and updating as required by the algorithm used.

Remarks:

- In some steps additional computational work is necessary if specific algorithmic techniques are used (details later).
- To find a first feasible solution phase-1 algorithms can be defined that use practically the above algorithmic steps with slight modifications.

SPECIAL FEATURES OF LARGE-SCALE LP PROBLEMS

While the original version of the SM can be coded in about 30 lines of a high level programming language (Fortran, C/C++), an implementation of this type is utterly useless for solving real-life (industry strength) LP problems.

Such problems are large in size and possess some important features. In brief, they are sparsity, structure, fill in, and susceptibility to numerical troubles. To properly handle these features sophisticated data structures and algorithmic units are needed in order to successfully solve real large-scale problems of several hundreds of thousands constraints and variables.

The most important of the special features is *sparsity* (often referred to as *low density*). Sparsity means that the ratio of nonzero elements in an entity (matrix or vector) to the total number of elements is very small. An interesting experience shows that, on an average, there are 5–10 nonzeros in a column of $\bar{\mathbf{A}}$ independent of the actual size of the problem. It implies that larger problems are increasingly more sparse. According to this “rule” the average density is not more than 0.1% for problems with around 10,000 rows. There is a collection of LP problems, which is widely used for testing and comparing algorithms. It is available on the internet from netlib/lp/data.

Many large-scale LP problems possess some *structure*, like the ones that represent dynamic models, spatial distribution, or uncertainty. Such problems contain several, often identical, blocks that are just loosely connected by some constraints and/or variables having nonzero coefficients in the rows/columns of several blocks. Structure

Figure 1. Nonzero pattern of GREENBEA.MPS. Problem size: 2393 rows (including the objective function), 5405 columns, 31,499 nonzeros.

can be visualized by displaying the *nonzero pattern* of the $\mathbf{A}$ matrix. There exist several software tools that enable such visualization. These viewers are very useful tools as they can reveal unknown properties of LP models and also can suggest good solution strategies. Figure 1 shows the nonzero structure of netlib problem GREENBEA.MPS.

The third characteristic feature can be observed during simplex iterations. It is called *fill in*. If the tableau form of the SM is used it is updated by an *elementary transformation matrix* (ETM) $\mathbf{E}$ after every basis change. Although the matrices of large-scale problems are sparse, they tend to fill in. It means that, as a result of premultiplying (the already transformed) $\mathbf{A}$ by an $\mathbf{E}$, nonzeros can appear in places of zeros. Nonzeros can spread quickly and soon the entire tableau can be full. It may cause serious difficulties. For instance, in case of a $10,000 \times 20,000$ matrix, the original number of nonzeros can be around 100,000 (five per column); these many numbers can easily be accommodated in the memory of a personal computer. However, if it fills up then 200,000,000 nonzeros have to be stored and transformed in subsequent iterations, which is prohibitively large. This is where the RSM comes in (see later).

The fourth important feature is *susceptibility to numerical troubles*. It is not a surprise as this phenomenon is quite well known in computational linear algebra. Since cancelation, rounding, and truncation errors can accumulate, the solution algorithm can go wrong not only numerically but also logically (e.g., feasible problem declared infeasible, wrong basis declared optimal, and solution found unbounded instead of optimal). Numerical issues have triggered substantial improvements in computational techniques of the SM.

ADVANCED IMPLEMENTATION OF THE SIMPLEX METHOD

The subsequent discussion is mostly based on Maros [4]. Readers interested in more details are referred to this research monograph.

Requirements of LP Solvers

As the development of LP software is a major effort, it is reasonable to expect that the codes possess some desirable properties. The most important ones are briefly summarized below.

Robustness. A wide range of problems can be solved successfully. If the attempt is unsuccessful, a meaningful answer is returned (e.g., unrecoverable numerical troubles). Robustness implies reliability and accuracy.

Efficiency. In simple terms, efficiency means high execution speed.

Capacity. Large and difficult problems can be solved on a given computer configuration.

Portability. The system can be used on different hardware and software platforms.

Memory Scalability. The solver can adjust to the size of the main memory and operate reasonably efficiently if at least a minimum amount of memory is available. (The solver is not critically memory-hungry.) At the same time, it can adapt well if more memory is allocated.

Extensibility. The code permits both the simple addition of new features internally to the product and the straightforward integration of that product as a building block for other code.

These properties can be ensured partly during algorithm design and partly in the implementation phase.

Representation of LP Problems

LP problems are usually created by some modeling systems that provide a file containing problem data ($\mathbf{A}$, $\mathbf{c}$, $\mathbf{l}$, $\mathbf{u}$, and $\mathbf{b}$) in a format that is understood by a solver. It is called the *external representation* of LP problems. Interestingly, the only internationally recognized *de facto* standard is the MPS input format which was created in the 1950s. Though it is

considered very outdated, every solver is prepared to accept problems in this format. Thus, it is the means of communicating problems among solvers.

The original version is called *fixed MPS format* that uses fixed format records of no more than 80 characters. It reflects the ancient punched card structure. Rows and columns of the matrix of constraints are identified by names of no more than eight characters. The file is subdivided into sections introduced by an indicator record containing a section name (NAME, ROWS, COLUMNS, RHS, RANGES, BOUNDS) or end of file (ENDATA).

Indicator records, names, and numerical values have to be given in well-defined fixed positions. Only the nonzero elements have to be supplied in a column-wise order, each column starting with a new column name. Within a column, each nonzero is identified by its position (row name). Components of vectors (**c**, **l**, **u**, and **b**) are also identified by column or row names. The objective row must be included in the matrix as a nonbinding constraint (row). Surprisingly, the sense of optimization (min or max) cannot be defined in the MPS file. It must be given as a run parameter at solution time.

The heavy restrictions of the MPS format have led to the acceptance of a bit relaxed version of it, which is usually referred to as *free MPS format*. Here, the length of names is not limited; each field is separated from the next by one or more space characters. However, data must appear in the same sequence as in the fixed format. The free format is not standardized.

The first thing a solver does is reading the MPS file and converting its contents into an *internal representation*. This is logically quite a tricky operation that must be very quick. It calls for a fast MPS input unit, which is a “must have” for every advanced solver. During conversion, different statistics such as the number of rows/columns, number of nonzeros and density, number of variables by type, and some measures of the magnitude of elements are also created.

Preprocessing

Usually the immediate internal form of the constraints is

$$L_i \leq \sum_{j=1}^n a_{ij}x_j \leq U_i, \quad i = 1, \dots, m$$

$$\ell_j \leq x_j \leq u_j \quad j = 1, \dots, n.$$

By preprocessing the problem is brought into an equivalent form that can be solved more efficiently and accurately. The main aims are to reduce the size of the problem, detect infeasibility/unboundedness of the problem without solving it, and improve numerical characteristics. Typical actions of preprocessing are presolve and scaling.

Presolve. During *presolve*, a sequence of increasingly stringent tests is performed. The most frequently used test can (i) identify contradicting individual bounds, (ii) detect empty rows, (iii) detect empty columns, (iv) identify singleton rows and convert them into individual bounds, (v) remove fixed variables, (vi) identify redundant and forcing constraints, (vii) tighten/relax individual bounds, (viii) identify implied free variables, (ix) detect singleton columns to impose constraints on their reduced costs, (x) identify dominated variables, and (xi) reduce density of the matrix.

The reduction in problem size, number of nonzeros, and density can be quite substantial.

Scaling. After presolve, it is often advisable to perform *scaling* on the problem. It can improve the numerical characteristics. However, there is no guarantee for the success but in most cases it is worth doing it.

Scaling in the LP context is a linear transformation of the matrix of constraints whereby each row and each column is multiplied by a real number called *scale factor*. It entails the adjustment of the right-hand side, objective function, and bounds. Formally, scaling is equivalent to pre- and postmultiplying **A** by diagonal matrices, such that

$$\mathbf{RAC}\bar{\mathbf{x}} = \mathbf{Rb},$$

with $\mathbf{R} = \text{diag}(R_1, \dots, R_m)$, $\mathbf{C} = \text{diag}(C_1, \dots, C_n)$, where R_i and C_j are the scale factors, and $\mathbf{C}\bar{\mathbf{x}} = \mathbf{x}$. From the latter

$$\bar{\mathbf{x}} = \mathbf{C}^{-1}\mathbf{x}.$$

Obviously, the finite individual bounds of $\bar{x}_j$ are also transformed to u_j/C_j and, similarly, the explicit lower bounds, if given, to ℓ_j/C_j . The objective row is not scaled row-wise. However, the computed column scale factors can be applied to it in which case the objective values of the scaled and unscaled problems are the same. It can be useful when the iterations are monitored.

The importance of scaling in computational linear algebra has long been known. Unfortunately, its role in LP is not that well understood. There are examples where scaling makes it possible to solve an otherwise unsolvable problem but there are other examples where just the opposite occurs: a problem cannot be solved when scaled but becomes easily solvable without scaling. The main difference between traditional linear algebra and LP is that the former works with the matrix of a fixed set of equations while in LP the set of (basic) equations keeps changing and each of them may require a different scaling. What can be done cheaply in LP is a one-off scaling of $\mathbf{A}$ which then applies to all bases selected by the SM.

There are several methods to determine generally good row and column scale factors.

Equilibration. It is a well-established standard method. Each row is scaled to make the largest absolute element equal to 1. It is achieved by multiplying the row with the reciprocal of the largest absolute element (so the row scale factors are these reciprocals). It is followed by a similar scaling for the columns (i.e., the column scale factors are the reciprocals of the absolute maximum values in a column). As a result, the largest absolute element in each row and each column will be 1.

Geometric Mean. For each row, the

$$\left(\max_j \{|a_{ij}|\} \times \min_j \{|a_{ij}|\} \right)^{\frac{1}{2}}$$

quantity is computed and its reciprocal (or its nearest power of 2 to avoid rounding error) is used to multiply the nonzeros of the row. A similar action is taken for each column.

Arithmetic Mean. Each row is multiplied by the reciprocal of the arithmetic mean of the nonzero elements in the row (or the nearest power of 2), followed by a similar action for the columns.

In practice, these simple methods are used in combination, one after the other. If round-off is not an issue, the last method in a combination is always equilibration. The reason for it is that it creates some ground to setting some absolute tolerances for the solver. As such, a typical combination is geometric mean followed by equilibration.

Curtis and Reid [5] have proposed a scaling that is optimal in some sense. It requires the solution of a quadratic optimization problem which may sound too complicated. However, in practice just a few iterations give very good approximations and thus the computational demand is not very excessive and the quality is usually very good. For details the reader is referred to Curtis and Reid [5] or Maros [4] (pp. 113–116).

After presolve and scaling, the remaining problem is augmented with a unit matrix of logical variables that make every constraint an equality, as in Equation (1).

When the problem is solved every action of preprocessing has to be undone so that the solution is obtained in terms of the original problem.

Factorization of the Basis

The two main matrix–vector operations in the SM are computing $\alpha = \mathbf{B}^{-1}\mathbf{a}$ and $\pi^T = \mathbf{r}^T\mathbf{B}^{-1}$ with some $\mathbf{a}$ and $\mathbf{r}$ vectors. In both cases the inverse of the basis is used. The required α and π vectors can also be determined as the solutions of two systems of linear equations if the above equations are rearranged: $\mathbf{B}\alpha = \mathbf{a}$ and $\mathbf{B}^T\pi = \mathbf{r}$.

In the first case, the inverse of the basis or some equivalent form is needed that can be used to perform the above operations. In practice, the PFI turned out to be the most appropriate equivalent representation. $\mathbf{B}^{-1}$ is written as $\mathbf{B}^{-1} = \mathbf{E}_s\mathbf{E}_{s-1} \cdots \mathbf{E}_1$, where each

$\mathbf{E}_i$ is an ETM that differs from the unit matrix in just one column which is usually referred to as *eta* (η) vector. Only these etas need to be stored together with their position in the matrix. In each iteration a new ETM (eta) is created from the updated incoming column which is simply added to the list of ETMs. The introduction of PFI [2] has revolutionized the SM and it became capable of solving real large sparse LP problems.

As some weaknesses of PFI have surfaced (numerical difficulties, quick growth of the number of nonzeros in the etas, need for frequent reinversion) attention has turned to the second possibility, that is, the solution of systems of equations. The breakthrough was the introduction of the LU representation of the basis, $\mathbf{B} = \mathbf{LU}$, where $\mathbf{L}$ is a lower and $\mathbf{U}$ is an upper triangular matrix. Operations with triangular matrices are very simple.

$\mathbf{B}\alpha = \mathbf{a}$ can be rewritten as $\mathbf{LU}\alpha = \mathbf{a}$. To obtain α , first $\mathbf{Ly} = \mathbf{a}$ is solved for $\mathbf{y}$ using *forward substitution* then $\mathbf{U}\alpha = \mathbf{y}$ is solved for α using *back substitution*. Both operations can be performed very efficiently once the LU form is available.

Creating the LU form is logically more complicated than that of PFI, in particular when we aim at a sparse form. However, efficient implementations exist [6]. There is one more difficulty. After every basis change the LU form is usually destroyed, and so must be restored. There are several techniques that can do this [7–11]. Details of efficient implementation of maintaining LU can be found in Suhl and Suhl [12].

Whether PFI or LU is used and updated after every basis change, the accuracy of them must be restored by periodical reinversion or refactorization, respectively. Experience shows that the advisable reinversion frequency for PFI is 30–50 iterations and the refactorization frequency is 100–150 iterations. The frequency is usually a parameter that has a good default value which, however, can be changed by the user. There are some requirements that these procedures must satisfy: (i) speedy operation to cause minimum delay in optimization, (ii) generation of sparse PFI or LU to speed up subsequent operations in the SM, and (iii) high numerical accuracy.

The overall success of a solver heavily depends on how the PFI or LU is implemented.

Initial Basis

Creation of a good initial basis is a big challenge. Even the notion of “good” is not uniquely defined. Some of the requirements are: the initial basis should (i) be as feasible as possible, (ii) have good objective value, (iii) be triangular. In practice, triangularity always takes priority followed by a combination of (i) and (ii). Obviously, determining an initial basis must be done in “no time,” that is, very quickly.

The all-logical basis corresponding to the ever present identity matrix is triangular and is immediately available. However, in most cases it is not a very good choice. Other triangular bases like the CPLEX basis [13] or CRASH (LTSF) [14] are much better candidates to determine an initial basis.

Optimization often starts from a previously saved basis or an optimal basis of a related problem. Solvers are prepared to accept such bases and even can overcome size compatibility problems.

Pricing

In the general step, the SM chooses an improving nonbasic variable to enter (dual: basic to leave) the basis. If none can be found the current solution is optimal. The rest of this discussion here refers to the primal simplex. Similar steps are valid for the dual.

Selection of an incoming variable is made by checking the optimality conditions for each nonbasic variable. This operation is often referred to as *pricing*. Any variable that violates its optimality condition is an improving candidate. This freedom has given rise to several pricing strategies. Currently none of them is known to be the best one.

From practical point of view, the best pricing strategy is the one that leads to an optimal solution with the least computational effort (shortest solution time). This would be a global strategy. However, in any specific iteration the SM can see only the neighboring bases. Therefore, we cannot expect more than a locally good selection.

It is typical that a large proportion of the total solution time is spent in pricing. Therefore, it is essential to economize this operation.

Regarding the strategies, two extremes can be identified: trying to minimize the number of iterations results in very slow iterations involving heavy computations per iteration and, on the other extreme, methods that have high iteration speed usually require a very large number of iterations until termination. There is no clear theoretical answer which is better but experience shows that usually it is worth making some extra effort to improve the quality of the choice.

In an iteration we can check all nonbasic reduced costs (*full pricing*), or only a subset of them if a sufficient number of improving candidates have already been found (*partial pricing*).

If the computed reduced costs are directly compared then we talk about *direct pricing*. If they are (perhaps approximately) brought to some common platform for comparison then it is termed *normalized pricing*.

The motivation for normalized pricing is the following.

The reduced cost of variable x_j is $d_j = c_j - \pi^T \mathbf{a}_j$, where π is the simplex multiplier. The actual value of d_j depends on the column scale. Namely, if $\hat{\mathbf{a}}_j = s_j \mathbf{a}_j$ and $\hat{c}_j = s_j c_j$, where $s_j > 0$ is the scale factor, then

$$\hat{d}_j = \hat{c}_j - \pi^T \hat{\mathbf{a}}_j = s_j(c_j - \pi^T \mathbf{a}_j) = s_j d_j.$$

Therefore, if the magnitude of the reduced cost is used in comparison the result may be misleading. However, we can obtain a scale-independent measure for d_j if we apply the following *dynamic scaling*:

$$\tilde{d}_j = \frac{d_j}{\|\alpha_j\|}, \quad (2)$$

where $\|\cdot\|$ denotes the Euclidean norm and $\alpha_j = \mathbf{B}^{-1} \mathbf{a}_j$. To see the scale independence of $\tilde{d}_j$, we note that $\hat{\alpha}_j = \mathbf{B}^{-1} \hat{\mathbf{a}}_j = s_j \mathbf{B}^{-1} \mathbf{a}_j = s_j \alpha_j$, and, therefore,

$$\|\hat{\alpha}_j\| = s_j \|\alpha_j\|.$$

So, if the scaled column $\hat{\mathbf{a}}_j$ is used instead of $\mathbf{a}_j$ then both the numerator and denominator are multiplied by s_j in Equation (2). Therefore, $\tilde{d}_j$ remains unchanged. Column selection on the basis of Equation (2) is called *steepest edge pricing* (some details later).

In *hierarchical pricing*, we rank the checked improving candidates according to some further criteria (e.g., expected steplength). This technique requires the setting up of a multiplier vector per criterion (each is equivalent to solving $\mathbf{B}^T \mathbf{v} = \mathbf{h}$ for $\mathbf{v}$) and an extra dot product for each candidate.

It is possible to select some of the most promising candidates during a pricing pass and do iterations with the current basic variables and the selected few. This method is referred to as *multiple pricing*. The selection of candidates is called a *major iteration* (actually, no iteration but selection is done) and the subsequent iterations are *minor iterations*. If the selected subproblem is solved entirely we talk about *complete suboptimization*, if the process terminates when none of the selected candidates can be entered with a positive gain we call it *partial suboptimization*.

Multiple pricing has several attractive features. First of all, from the updated few columns we can select one that makes the largest improvement in the objective function. Second, multiple pricing can be effective in coping with degeneracy. Simply, if any of the selected candidates can result in a positive step, it will be chosen automatically. Third, if the pivot element in the chosen column is not of proper size, the remaining columns can be searched to find a better one, and it comes at no additional cost.

Though multiple pricing does not fit into all pricing strategies to be discussed, it is still an important technique and worth including in an advanced solver.

Below is a brief summary of the best known pricing strategies.

Dantzig Pricing. It is a full pricing selecting a variable with the most violating reduced cost. It is not a particularly good performer for large-scale problems.

Partial Pricing. If there are many improving candidates, a good choice of them can be

found by scanning only a part of the nonbasic variables. This practice is known as *partial pricing*. There are different tactics how to partition the matrix for pricing. We mention just a few. If the partitions are determined once we talk about *static partitioning*. The other possibility is to redefine the partitions as optimization progresses, called *dynamic partitioning*. In either case, pricing starts in the partition next to the one where it stopped during the previous iteration. This goes on in a wrap-around manner after the last partition was scanned. Within partitions, it is possible to do full or partial pricing. The latter is called *nested partial pricing*.

Sectional Pricing. Real-life LP problems often exhibit some structure. In such cases the nonzeros of matrix $\mathbf{A}$ are located in clusters. The projection of the clusters on the horizontal axis forms sections. Pointers can be set up to mark the boundaries of the sections. If partial pricing is done along the sections we talk about *sectional pricing*. This concept has a deeper meaning than just being a partial pricing.

It is typical that vectors in a section are more related to each other than to vectors in other sections. Therefore, if multiple pricing is used we can obtain unrelated (or loosely related) vectors if they are picked from different sections which can lead to more meaningful minor iterations. Namely, in this case, we can expect that the inclusion of one of the candidates in the basis will not ruin the profitability of the remaining ones and they also can enter the basis.

More variations emerge if we do partial pricing within the sections and also do partial pricing with the sections themselves. It means that only a given number of sections are scanned per major iteration and partial pricing is done within the sections.

A general sophisticated pricing scheme is presented in Maros [15], which contains several known pricing strategies as special cases and also can be used to define new ones.

Steepest Edge Pricing. It is the most advanced normalized pricing. Computing dynamic scale factors based on Equation (2) would require prohibitively much

computational work. However, in Forrest and Goldfarb [16], an exact update formula has been proposed that reduces the extra computational work, though it is still substantial. At the same time, experience shows that among the known pricing strategies this one leads to the smallest number of iterations. It does not always translate into the shortest solution time. This very important pricing strategy is a “must have” for every advanced solver. It is a full pricing.

Devex Pricing. Historically, Devex [17] was the first normalized pricing algorithm. Today it is viewed as an approximate steepest edge method. The updated factors it uses gradually worsen. When the inaccuracy exceeds a user-defined level the scale factors are recomputed in a new reference framework. The dual version of Devex practically does not require extra computations. In primal the updated pivot row has to be determined which is computationally more or less equivalent with one more full pricing pass.

Ratio Test

The ratio test is specific to the algorithm (primal or dual) and the phase (phase-1 or phase-2). It is used to determine the basis change. In primal phase-1 and in both phases of dual piecewise linear functions can be defined that help determine the largest progress of the actual objective function with a selected incoming (dual: outgoing) variable. This technique has some additional advantages, like improved numerical stability, efficiency in the presence of degeneracy. For details, see Maros [4].

PROTOTYPE SIMPLEX-BASED SOLVER

In this section, the structure of a simplex-based prototype LP system is presented. An implementation must contain both the primal and the dual methods. Also, smooth transition from primal to dual iterations (and vice versa) should be made possible. Practice shows that the combination of the two main algorithms (one followed by the other to finish off or to make a correction if necessary) can result in the best performance.

Run Parameters, Parameter File

The operation of a simplex-based solver is controlled by several parameters. They can roughly be categorized as *string*, *algorithmic*, and *numerical* parameters.

String parameters are used to identify names (name of input file, output file, etc.). Algorithmic parameters describe the choice of main algorithm (primal, dual), direction of optimization (min, max), presolve strategy, starting basis, pricing, and so on. Numerical parameters define values of zero tolerances, frequencies (such as refactorization and saving of intermediate solutions), maximum number of nonimproving iterations before an antidegeneracy strategy is initiated, maximum number of iterations/solution time, and so on.

Run parameters are specified in a *parameter file*. Usually, every parameter has a default value that users can change by making modifications to the appropriate entry of this file.

Structure

The following functional units must be present in an advanced implementation.

Fast MPS Input. Converts a problem into internal representation. If memory allows it prepares not only column- but also a row-wise storage of $\mathbf{A}$ as some matrix-vector operations can be speeded up considerably with a row-wise $\mathbf{A}$. Provides statistics about the problem (m , $\bar{n}$, v_A , number of variables and constraints by type, density of $\mathbf{A}$, number of nonzeros in the objective row, right-hand side, and range).

Advanced versions of this functional unit are able to analyze the problem and suggest a solution strategy. They can also display the nonzero pattern of $\mathbf{A}$ with zoom facility and produce further statistics about the distribution of magnitudes of the nonzero elements. Visual inspection of the matrix can help select a good pricing strategy.

Preprocessing. Presolve and scaling are usually optional. The level of presolve (the actual tests to be performed) can also be controlled. Different versions of scaling can

be included to provide a choice. The IBM method of Benichou *et al.* [18] is a good candidate if the problem is stable enough to tolerate the small round-off errors generated by this method (the majority of the problems are such). However, for numerically demanding problems the Curtis-Reid scaling is better and should also be made available. Finally, it is important to allow the option of “no scaling,” as the LP relaxation of most combinatorial problems are best solved in this way.

Starting Procedures. The absolute minimum is the lower logical basis. Additionally, at least one of the crash techniques, generally CRASH (LTSF) or a variant of it, must also be available. It makes sense to implement an upper triangular crash on the basis of the same ideas as LTSF, which could be called *UTSF*. In this case, there is no lower triangular part and the LU form update can be very efficient, at least at the beginning of the iterations.

Factorization (LU), or Inversion (PFI). The LU form is highly preferred because of its proven superiority. As the PFI is easier to implement and performs quite well it can be the choice for a first working version of an LP system. Great care must be exercised when designing the data structures to enable the replacement of PFI by LU at a later stage.

Updating Triangular Factors for the LU Version. While the product form update is also a realistic alternative for the LU, the triangular update is more efficient. It leads to a slower growth of nonzeros which, in turn, reduces the need for too frequent refactorizations.

Pricing Strategies. If memory allows solvers usually maintain the vector of reduced costs, $\mathbf{d}$, and update it after every basis change. This applies to primal phase-2. As the composition of the objective function keeps changing in primal phase-1, it is reasonable to recompute the corresponding reduced costs as updating would be too complicated. For dual phase-2 the dual reduced costs (the primal basic variables)

are explicitly available. The dual phase-1 reduced costs are usually recomputed as the structure of the dual phase-1 objective function may change in every iteration.

Regarding the selection of the incoming (in primal) or outgoing (in dual) variables, usually many of the discussed pricing methods are available. Mostly some normalized pricing (Devex but possibly steepest edge) is recommended in both primal and dual. If SIMPRI of Maros [15] is implemented, its parameters can be adjusted to obtain a specific nonnormalized pricing method.

Column and Row Update. The selected column(s) (in primal) or row (in dual) have to be updated. This is a computationally demanding procedure. It is important to be able to exploit sparsity or even hyper-sparsity [19] of the vectors involved. Row- and column-wise storage of $\mathbf{A}$ and a sophisticated double storage of $\mathbf{U}$ of the LU decomposition are the main sources of speed in this part of the SM.

If either the simplex multiplier π or the vector of reduced costs $\mathbf{d}$ is kept updated it also gets transformed here.

Pivot Methods. This is actually the ratio test according to the main algorithm (primal or dual) and the feasibility (phase-1 or -2) for determining the outgoing (in primal) or incoming (in dual) variable. The quoted piecewise linear functions are the best performers as they make the greatest progress and also care for the numerical stability and are efficient in the presence of degeneracy.

Control Unit. Its first task is to interpret the parameter file, if present. It monitors and supervises the entire solution process, invokes functional units, evaluates their outcome, makes decision on the algorithmic techniques, triggers refactorization (reinversion), changes solution strategy if necessary (e.g., checks whether an antidegeneracy strategy has to be applied and makes decision on pricing strategy). It can be quite sophisticated in case of an implementation that has a considerable algorithmic richness.

Solution Output. The solution must be presented in the “unpresolved” form which is

usually obtained after the appropriate *post-solve* procedure (to undo presolve) has been applied. Complete primal and dual solutions can be sent to a file for possible further processing. Usually one line for each variable and constraint is prepared containing some replicated input data (name, variable/row type, lower and upper bound, objective coefficient/RHS value, range) and computed values (primal and dual variables). It is useful to include some additional information by marking basic variables and variables at bound. If the solution is infeasible variables at infeasible level are also marked. If a modeling system was used this file is probably retrieved by it. Otherwise, the file can be perused or submitted to a special purpose program for further analysis, processing, and presentation.

In advanced solvers, upon request, sensitivity analysis of the optimal solution can be performed. It can help make a statement about the robustness of the solution.

FURTHER READINGS

State-of-the-art optimizers are valued commercial products. Therefore, their authors are not keen to disclose details of the solvers. They usually benefit from results of academic research that appear in the open literature.

Recently, academic solvers started to catch up with the commercials in terms of speed and reliability. The commercials are still leading in algorithmic richness. They may have simplex, interior point methods, quadratic programming, integer LP, network optimization, and so on.

In addition to the already quoted source [4] which gives a relatively comprehensive treatment of the SM, and other quoted sources, the journal papers [19–27] give further insight into simplex-based solvers.

INTRODUCTION

The concept of expected utility provides a powerful framework for modeling decision making under risk. To compare two alternatives, we just need to compare their expected utilities. A potential obstacle here is that eliciting utility functions might be difficult. In a consulting context, a consultant might have to suggest a course of action without having the opportunity to elicit a corporate utility function. In a group decision making context, different parties might have different utilities, but if every group member prefers the same alternative, the difference in individual utilities is irrelevant.

Therefore, if two alternatives can be compared in a way that sets some of the particulars of the utility function aside, the situation is simplified, the resulting decision is more reliable, and might be acceptable to a wider group of involved parties. The concept of stochastic dominance offers that type of comparison. It is a formal

statistical property, allowing partial ranking of probability distributions. If one alternative is preferred to another in the sense of the first-order stochastic dominance, then any decision maker with an increasing utility function would have the same preference. If one alternative is preferred to another in the sense of the second-order stochastic dominance, then any decision maker with an increasing and concave utility would have the same preference. Similar analogies hold for higher orders. In the case of multiple choices, even if stochastic dominance criterion does not provide complete ordering of all possible decisions, it might help to eliminate the dominated ones, so that more thorough analysis will focus on the subset of the most promising alternatives. The inferior alternative(s) can be formally identified via the concept of convex stochastic dominance [1,2].

Fishburn and Vickson [3], Whitmore and Findlay [4], and Levy [5] provide comprehensive surveys of stochastic dominance literature. Empirical tests for stochastic dominance efficiency using the notion of convex stochastic dominance are described in, e.g., Refs 6 and 7. Our article focuses on more recent results that highlight the link between stochastic dominance of different orders.

The next section presents several equivalent definitions of stochastic dominance, and explains the connection with the expected utility framework. After stating formal general results, we discuss and illustrate them at the intuitive level. The section titled “Stochastic Dominance as the Preference for Combining Good with Bad” shows that stochastic dominance of different orders can be connected via the preference for combining good with bad, while the next section presents the applications.

STOCHASTIC DOMINANCE AND Nth-DEGREE RISK

We start with a definition of stochastic dominance [8–10]: Assume that all random

variables have bounded supports contained within the interval $[a, b]$. Let F denote the cumulative distribution function (cdf) for such a random variable. Define $F^{(0)}(x) \equiv F(x)$ and define $F^{(i)}(x) \equiv \int_a^x F^{(i-1)}(t) dt$ for $i \geq 1$.

Definition 1. Distribution F weakly dominates Distribution G in the sense of N th-order stochastic dominance if

1. $F^{(N-1)}(x) \leq G^{(N-1)}(x)$ for all $a \leq x \leq b$,
2. $F^{(i)}(b) \leq G^{(i)}(b)$ for $i = 1, \dots, N-2$.

We write F NSD G to denote that F dominates G via N th-order stochastic dominance. If the random variables $\tilde{X}$ and $\tilde{Y}$ have cdfs $\tilde{F}$ and $\tilde{G}$ respectively, we will also say that $\tilde{X}$ NSD $\tilde{Y}$.

Integrals of cdfs, appearing in Definition 1, can be expressed via lower partial moments:

$$\int_a^x (x-t)^k dF(t) = (k!)F^{(k)}(x), \quad k = 1, 2, \dots \quad (1)$$

Equation (1) follows from integration by parts:

$$\begin{aligned} \int_a^x (x-t)^k dF(t) &= (x-t)^k F(t) \Big|_{t=a}^{t=x} \\ &\quad + k \int_a^x (x-t)^{k-1} dF^{(1)}(t), \end{aligned}$$

where the first term is zero since $F^{(k)}(a) = 0$ and $(x-t)^k \Big|_{t=x}^{t=x} = 0$. Repeating the integration by parts $(k-1)$ times yields Equation (1).

The following theorem expresses the well-known links between stochastic dominance and expected utility. [Hadar and Russell [11] and Hanoch and Levy [12], introduced this notion into the economics literature for second-order stochastic dominance. See Refs 9 and 13, as well as [8], for extensions to higher orders of stochastic dominance.] Here $u(x)$ denotes the individual's utility function. For notational convenience, we use $u^{(n)}(x)$ to denote $\frac{d^n u(x)}{dx^n}$.

Theorem 1. The following statements are equivalent:

1. F dominates G in the sense of N th-order stochastic dominance,
2. $\int_a^b u(x) dF(x) \geq \int_a^b u(x) dG(x)$, for all functions u such that $\text{sgn } u^{(n)}(x) = (-1)^{n+1}$ for $n = 1, \dots, N$.

Proof. Integrating by parts, the difference in expected utility for the distributions F and G can be expressed as

$$\begin{aligned} \int_a^b u(x) dF(x) - \int_a^b u(x) dG(x) &= u(x)[F(x) - G(x)] \Big|_{x=a}^{x=b} \\ &\quad + (-1) \int_a^b u^{(1)}(x) d[F^{(1)}(x) - G^{(1)}(x)] \\ &= (-1) \int_a^b u^{(1)}(x) [F^{(0)}(x) - G^{(0)}(x)] dx. \end{aligned}$$

Repeating the integration by parts $(N-1)$ times yields

$$\begin{aligned} \int_a^b u(x) dF(x) - \int_a^b u(x) dG(x) &= \sum_{k=1}^{N-1} (-1)^k u^{(k)}(b) [F^{(k)}(b) - G^{(k)}(b)] \\ &\quad + (-1)^N \int_a^b u^{(N)}(x) [F^{(N-1)}(x) - G^{(N-1)}(x)] dx. \end{aligned}$$

Therefore, the first claim of the theorem implies the second.

Equation (1) is useful to prove that the second claim of the theorem implies the first. Consider $u(t) = -(b-t)^k$, $k = 1, \dots, N-2$. Then

$$\begin{aligned} \int_a^b u(t) dF(t) &\geq \int_a^b u(t) dG(t) \\ \Leftrightarrow \int_a^b (b-t)^k dG(t) &\geq \int_a^b (b-t)^k dF(t) \\ \Leftrightarrow F^{(k)}(b) &\leq G^{(k)}(b). \end{aligned}$$

Similarly, consider

$$u(t) = \begin{cases} -(x-t)^{N-1} & \text{if } t \leq x \\ 0 & \text{if } t > x \end{cases}.$$

Then

$$\begin{aligned} \int_a^b u(t) dF(t) &\geq \int_a^b u(t) dG(t) \\ \Leftrightarrow \int_a^x (x-t)^{N-1} dG(t) &\geq \int_a^x (x-t)^{N-1} dF(t) \\ \Leftrightarrow F^{(N-1)}(x) &\leq G^{(N-1)}(x). \end{aligned}$$

Stochastic dominance of order N implies stochastic dominance of any higher order. To isolate the N th-order effect from the ones of lower orders, Ekmann [14] introduced the concept of N th-degree risk. The special case where $N = 2$ was introduced much earlier by Rothschild and Stiglitz [15], who call this case a “mean-preserving increase in risk.”

Definition 2. Distribution F has more N th-degree risk than Distribution G if

1. $F^{(N-1)}(x) \leq G^{(N-1)}(x)$ for all $a \leq x \leq b$,
2. $F^{(i)}(b) = G^{(i)}(b)$ for $i = 1, \dots, N-1$.

The following corollary to Theorem 1 relates the concept of N th-degree risk to the expected utility framework.

Corollary 1. The following statements are equivalent:

1. G has more N^{th} -degree risk than F ,
2. $\int_a^b u(x) dF(x) \geq \int_a^b u(x) dG(x)$, for all functions u such that $\text{sgn } u^{(N)}(x) = (-1)^{N+1}$.

As follows from Equation (1), G has more N th-degree risk than F if and only if F NSD G and the first $N-1$ moments of F and G are identical.

How could we visualize those stochastic dominance relations at the intuitive level? To construct a pair of random variables ordered by the first-order stochastic dominance, we can take any random variable $\tilde{X}$ and add to it a nonpositive random variable $\tilde{Z}$. Then $\tilde{X} + \tilde{Z}$ is first-order dominated by $\tilde{X}$. For the second-order dominance, $\tilde{Z}$ can be a random variable with nonpositive conditional mean (i.e., $\mathbb{E}(\tilde{Z}|\tilde{X} = x) \leq 0$ for all x). Then $\tilde{X} + \tilde{Z}$ is second-order dominated by $\tilde{X}$.

In the examples above, $\tilde{X}$ can also be a degenerate random variable, that is, $\tilde{X} \equiv c$. Then, for any random variable $\tilde{Y}$, $\tilde{Y} \leq c$, we can say that $\tilde{Y}$ is first-order dominated by $\tilde{X} \equiv c$, and $\tilde{Y}$ is second-order dominated by $\tilde{X} \equiv \mathbb{E}(\tilde{Y})$. However, higher orders of stochastic dominance (or ordering by N th degree risk with $N > 2$) cannot be constructed with one random variable being degenerate. Indeed, suppose that $\tilde{X}$ and $\tilde{Y}$ can be ordered by N th degree risk with $N > 2$, while $\tilde{X} \equiv c$ is degenerate. By Definition 2, the first $N-1$ moments of $\tilde{X}$ and $\tilde{Y}$ are identical. Thus, $\text{Var}(\tilde{Y}) = \text{Var}(\tilde{X}) = 0$, and $\tilde{Y} = c$ almost surely. As an extension, if $\tilde{X}$ and $\tilde{Z}$ are two independent random variables, then a pair $(\tilde{X} + \tilde{Z}, \tilde{X})$ is either ranked by the first-order or second-order stochastic dominance, or cannot be ranked by stochastic dominance of any order.

The above discussion suggests that for stochastic dominance of order three and higher, we cannot have a degenerate probability distribution; both lotteries must be risky. A good illustration is the result of an experiment by Mao [16], which was used by Menezes *et al.* [17] to motivate the concept of aversion to downside risk (i.e., prudence that requires positive third-order derivative of the utility function). Consider the following two lotteries. Lottery A pays 1000 with a probability of $\frac{3}{4}$ and pays 3000 with a probability of $\frac{1}{4}$. Lottery B pays zero with a probability of $\frac{1}{4}$ and pays 2000 with a probability of $\frac{3}{4}$. Note that both lotteries exhibit the same first two moments in their distributions, and lottery A third-order stochastically dominates B. Individuals who prefer lottery A to lottery B exhibit “downside risk aversion.”

The concept of downside risk is related to the following decomposition: Define $\tilde{X}_1 \equiv 2000$, $\tilde{Y}_1 \equiv 1000$, $\tilde{X}_2 \equiv 0$, and $\tilde{Y}_2 \equiv [-1000, +1000]$, a 50–50 lottery. Note that $\tilde{Y}_1$ is a first-order increase in risk over $\tilde{X}_1$, $\tilde{Y}_2$ is a second-order increase in risk over $\tilde{X}_2$, A is the 50–50 lottery $[\tilde{X}_1 + \tilde{Y}_2, \tilde{Y}_1 + \tilde{X}_2]$, and B is the 50–50 lottery $[\tilde{X}_1 + \tilde{X}_2, \tilde{Y}_1 + \tilde{Y}_2]$. Thus, we can think of the following story for lotteries A and B: there are two equally likely states, and we receive 2000 in one state and 1000 in the other. Then, we are required to add a zero-mean risk $[-1000, 1000]$ to one of

the states. Lottery A (B) adds this risk to the state where we receive 2000 (1000). Third-order stochastic dominance (or downside risk aversion) is consistent with the preference to add risk to the higher-wealth state. An alternative view is related to the concept of “preceding changes in risk” [18]. We can start from lottery B, $[\tilde{X}_1 + \tilde{X}_2, \tilde{Y}_1 + \tilde{Y}_2]$, and make second-order improvement (replace $\tilde{Y}_2$ with $\tilde{X}_2$) at lower wealth level ($\tilde{Y}_1 \equiv 1000$), followed by second-order deterioration of the same size (replace $\tilde{X}_2$ with $\tilde{Y}_2$) at a higher-wealth level ($\tilde{X}_1 \equiv 2000$). That would yield lottery A. Here the second-order improvement precedes (in terms of wealth) second-order deterioration, and thus leads to the third-order improvement.

To conclude, the example above is consistent with the preference for combining good with bad, resulting in the lottery $[\tilde{X}_1 + \tilde{Y}_2, \tilde{Y}_1 + \tilde{X}_2]$, as opposed to combining good with good and bad with bad, leading to the lottery $[\tilde{X}_1 + \tilde{X}_2, \tilde{Y}_1 + \tilde{Y}_2]$, where $\tilde{X}_i$ dominates $\tilde{Y}_i$ in the sense of i th-order stochastic dominance, $i = 1, 2$. The next section states and proves how stochastic dominance of different orders (and different orders of risk) can be characterized by a particular preference for combining good with bad.

STOCHASTIC DOMINANCE AS THE PREFERENCE FOR COMBINING GOOD WITH BAD

Let $[A, B]$ denote a lottery that pays either A or B , each with probability one-half. Consider the mutually independent random variables $\tilde{X}_N, \tilde{Y}_N, \tilde{X}_M$, and $\tilde{Y}_M$, and assume that $\tilde{X}_i$ dominates $\tilde{Y}_i$ via i th-order stochastic dominance for $i = M, N$. We wish to compare the 50–50 lotteries $[\tilde{X}_N + \tilde{Y}_M, \tilde{Y}_N + \tilde{X}_M]$ and $[\tilde{X}_N + \tilde{X}_M, \tilde{Y}_N + \tilde{Y}_M]$.

Theorem 2. [19]. *Suppose that $\tilde{X}_i$ dominates $\tilde{Y}_i$ via i th-order stochastic dominance for $i = M, N$. The lottery $[\tilde{X}_N + \tilde{Y}_M, \tilde{Y}_N + \tilde{X}_M]$ dominates the lottery $[\tilde{X}_N + \tilde{X}_M, \tilde{Y}_N + \tilde{Y}_M]$ via $(N + M)$ th-order stochastic dominance.*

Proof. Let T be a positive integer and define $\mathbb{U}_T \equiv \{u \mid \text{sgn } u^{(n)}(w) = (-1)^{n+1} \text{ for}$

$n = 1, \dots, T\}$. For an arbitrary function $u \in \mathbb{U}_{N+M}$, define $v(w) \equiv \mathbb{E}u(\tilde{Y}_M + w) - \mathbb{E}u(\tilde{X}_M + w)$, where $\mathbb{E}$ denotes the expectation operator. We first show that $v \in \mathbb{U}_N$. To see this, consider any integer k , $1 \leq k \leq N$. Observe that $(-1)^k u^{(k)} \in \mathbb{U}_{N+M-k} \subset \mathbb{U}_M$, and therefore $\text{sgn } v^{(k)}(w) = \text{sgn } [\mathbb{E}u^{(k)}(\tilde{Y}_M + w) - \mathbb{E}u^{(k)}(\tilde{X}_M + w)] = (-1)^{k+1}$. The second equality above follows from $(-1)^k u^{(k)} \in \mathbb{U}_M$ and $\tilde{X}_M$ MSD $\tilde{Y}_M$. Thus, $v \in \mathbb{U}_N$.

The condition that $\tilde{X}_N$ dominates $\tilde{Y}_N$ via N th-order stochastic dominance, together with $v \in \mathbb{U}_N$, implies that $\mathbb{E}v(\tilde{X}_N) \geq \mathbb{E}v(\tilde{Y}_N)$, which by the definition of v is equivalent to

$$\begin{aligned} \mathbb{E}u(\tilde{X}_N + \tilde{Y}_M) - \mathbb{E}u(\tilde{X}_N + \tilde{X}_M) \\ \geq \mathbb{E}u(\tilde{Y}_N + \tilde{Y}_M) - \mathbb{E}u(\tilde{Y}_N + \tilde{X}_M). \end{aligned}$$

Rearranging terms above, this inequality is equivalent to

$$\begin{aligned} \frac{1}{2} \{ \mathbb{E}u(\tilde{X}_N + \tilde{Y}_M) + \mathbb{E}u(\tilde{Y}_N + \tilde{X}_M) \} \\ \geq \frac{1}{2} \{ \mathbb{E}u(\tilde{X}_N + \tilde{X}_M) + \mathbb{E}u(\tilde{Y}_N + \tilde{Y}_M) \}, \end{aligned}$$

which is precisely the lottery preference claimed in the theorem.

Theorem 2 expresses a preference for lotteries that combine “relatively good” assets with “relatively bad” ones, where relatively good and bad are defined via stochastic dominance. It is analogous to the notion of “disaggregating the harms” as discussed by Eeckhoudt and Schlesinger [20], if we interpret the “harms” as sequentially replacing each of the $\tilde{X}$ random variables with a $\tilde{Y}$ random variable in the sum $\tilde{X}_N + \tilde{X}_M$.

These preferences lead to a partial ordering of the four alternative sums of random variables, based upon stochastic dominance criteria:

$$\begin{aligned} \tilde{X}_N + \tilde{X}_M > \tilde{X}_i + \tilde{Y}_j > \tilde{Y}_N + \tilde{Y}_M \\ \text{for } (i, j) \in \{(M, N), (N, M)\}. \end{aligned} \quad (2)$$

Note that the sums $\tilde{X}_M + \tilde{Y}_N$ and $\tilde{X}_N + \tilde{Y}_M$ cannot be ordered via stochastic dominance.

In the spirit of Menezes and Wang [21], we can refer to these two sums as the “inner risks” and the sums $\tilde{X}_N + \tilde{X}_M$ and $\tilde{Y}_N + \tilde{Y}_M$ as the “outer risks.” Theorem 2 thus expresses a preference for a 50–50 lottery over the two inner risks as opposed to a 50–50 lottery over the two outer risks. If all lotteries in Equation (2) are degenerate (in which case $M = N = 1$), preference for a lottery over the two inner risks as opposed to a lottery over the two outer risks reduces to the standard notion of risk aversion.

The following Corollary extends Theorem 2 to Ref. 14’s ordering by N th-degree risk.

Corollary 2. *Suppose that $\tilde{Y}_i$ has more i^{th} -degree risk than $\tilde{X}_i$ for $i = M, N$. Then the lottery $[\tilde{X}_N + \tilde{X}_M, \tilde{Y}_N + \tilde{Y}_M]$ has more $(N + M)$ th-degree risk than the lottery $[\tilde{X}_N + \tilde{Y}_M, \tilde{Y}_N + \tilde{X}_M]$.*

Stochastic Dominance and Correlation Aversion

Theorem 2 is also consistent with the notion of correlation aversion [22], as discussed in Ref. 23. Denote by I and I' two binary random variables, with marginal distributions taking either 0 or 1 with probability 1/2. Lottery $[\tilde{X}_N, \tilde{Y}_N]$ can be thought of as the random variable $I\tilde{X}_N + (1 - I)\tilde{Y}_N$, and lottery $[\tilde{X}_M, \tilde{Y}_M]$ can be thought of as the random variable $I'\tilde{X}_M + (1 - I')\tilde{Y}_M$. Summing these two random variables gives

$$I\tilde{X}_N + (1 - I)\tilde{Y}_N + I'\tilde{X}_M + (1 - I')\tilde{Y}_M. \quad (3)$$

Theorem 2 compares the 50–50 lotteries $A = [\tilde{X}_N + \tilde{Y}_M, \tilde{Y}_N + \tilde{X}_M]$ and $B = [\tilde{X}_N + \tilde{X}_M, \tilde{Y}_N + \tilde{Y}_M]$, where A combines good with bad, while B combines good with good and bad with bad. Note that Lottery A corresponds to Equation (3) with $I' = 1 - I$ and Lottery B corresponds to Equation (3) with $I' = I$. In that sense, A (B) corresponds to the perfect negative (positive) correlation between events I and I' , that specify lotteries $[\tilde{X}_N, \tilde{Y}_N]$ and $[\tilde{X}_M, \tilde{Y}_M]$. More generally, denote correlation between I and I' by ρ . Then Equation (3) becomes

$$\begin{aligned} & I\tilde{X}_N + (1 - I)\tilde{Y}_N + I'\tilde{X}_M + (1 - I')\tilde{Y}_M \\ &= \begin{cases} \tilde{X}_N + \tilde{X}_M & \text{with probability } \frac{1}{4}(1 + \rho), \\ \tilde{X}_N + \tilde{Y}_M & \text{with probability } \frac{1}{4}(1 - \rho), \\ \tilde{Y}_N + \tilde{X}_M & \text{with probability } \frac{1}{4}(1 - \rho), \\ \tilde{Y}_N + \tilde{Y}_M & \text{with probability } \frac{1}{4}(1 + \rho); \end{cases} \\ &= \begin{cases} [\tilde{X}_N + \tilde{X}_M, \tilde{Y}_N + \tilde{Y}_M] & \text{with probability } \frac{1}{2}(1 + \rho), \\ [\tilde{X}_N + \tilde{Y}_M, \tilde{Y}_N + \tilde{X}_M] & \text{with probability } \frac{1}{2}(1 - \rho). \end{cases} \end{aligned}$$

As this expression shows, increasing ρ increases the probability of the lottery that combines good with good and bad with bad (i.e., Lottery B), and decreases the probability of the lottery that combines good with bad (Lottery A). Therefore, by Theorem 2, increasing the correlation ρ is a deterioration in the sense of $(N + M)$ th-order stochastic dominance, consistent with the notion of correlation aversion.

The next section discusses how the concept of stochastic dominance, and Theorem 2 in particular, can be applied to decision making under uncertainty.

APPLICATIONS TO DECISION MAKING

As shown in the previous section, preferring more of an attribute to less and preferring to combine good lotteries with bad ones implies preferences consistent with stochastic dominance. Therefore, if the decision is about the alternatives that can be ordered by stochastic dominance, the choice can be made without computing the expected utility, and thus without knowing the particulars of the utility function. First, we discuss several contexts where the decision is about allocating good or bad random variables to a particular state. In such situations, we show how Theorem 2 can be used to determine the optimal allocation. Secondly, we discuss the connection between stochastic dominance (of arbitrary high order) and exponential utility.

Allocating Risks

The main building block in Theorem 2 is a lottery $[\tilde{X}, \tilde{Y}]$, resulting in either random

variable $\tilde{X}$ or random variable $\tilde{Y}$, with equal chances. There are several contexts where such a lottery might occur. One is a two-period consumption/saving model, where labor income in the first period is represented by the random variable $\tilde{X}$, and in the second period is represented by the random variable $\tilde{Y}$, as illustrated in the section titled “Precautionary Effects.” A second is a corporation with two headquarters and taxable profits, as illustrated in the section titled “Corporation with Two Headquarters.” A third is more “direct,” where the decision maker receives either $\tilde{X}$ or $\tilde{Y}$ with equal chances. Such a context is very useful to construct examples of stochastic dominance of higher orders, and to consider the effect of an independent additive background risk, as illustrated in the section titled “Tempering Effects of Risk.”

Precautionary Effects. Consider a simple two-period model of consumption and saving. An individual with time-separable preferences has a random labor income of $\tilde{X}$ at date $t = 0$ and income $\tilde{Y}$ at date $t = 1$. The individual decides to save some of her income at date $t = 0$ and to consume the rest. She must decide on how much to save before learning the realized value of $\tilde{X}$. Thus, her consumption at date $t = 0$ is $\tilde{X} - s$, where s is the amount saved. If $s < 0$, the consumer is borrowing money (i.e., negative savings) and consuming more than the realized value of $\tilde{X}$ at date $t = 0$. We assume that the interest rate for borrowing or lending is zero and that there is no time-discounting for valuing consumption at date $t = 1$. At this date, the individual consumes her income plus any savings, $\tilde{Y} + s$. Let s^* denote the individual’s optimal choice for savings.

Suppose that $\tilde{X}$ dominates $\tilde{Y}$ via N th-order stochastic dominance. For any nonnegative scalar $\varphi \geq 0$, since φ first-order dominates $-\varphi$, it follows from Theorem 2 that the 50–50 lottery $[(\tilde{X} - \varphi), (\tilde{Y} + \varphi)]$ dominates $[(\tilde{X} + \varphi), (\tilde{Y} - \varphi)]$ by $(N + 1)$ th-order stochastic dominance. Reinterpreting the “50–50 lottery” $[A, B]$ as sequential consumption of A at $t = 0$ and B at $t = 1$, Theorem 2 implies that saving an arbitrary amount $\varphi \geq 0$ always dominates saving the amount

$-\varphi$, whenever preferences satisfy $(N + 1)$ th-order stochastic dominance preference. It follows that we must have $s^* \geq 0$ for this individual.

For example, suppose that $\tilde{X} \equiv \mathbb{E}(\tilde{Y})$ and that preferences are given by expected utility. Then this result coincides with the classical case examined by Leland [24] and Sandmo [25], for the case where preferences display prudence, $u''' \geq 0$. This basic result extends in several directions:

- (i) Suppose that one’s labor income is risky in both periods, but it is riskier in the sense of a second-degree increase in risk at date $t = 1$. Anyone with preferences exhibiting an aversion to downside risk (i.e., prudence) would prefer to save money rather than to borrow money. If the second-period wealth is riskier in the sense of second-order stochastic dominance, a precautionary saving demand then requires both aversion to downside risk and aversion to mean-preserving spreads, as defined in Ref. 15.
- (ii) As opposed to (i), suppose that income in the second period is stochastically lower in the sense of first-order stochastic dominance. In that case, aversion to downside risk is no longer required to generate a demand for precautionary saving. We only need someone to be risk averse, that is, averse to risk increases of degree two.
- (iii) We obtain the general case stated above if first-period wealth dominates second-period wealth via N th-order stochastic dominance: A precautionary demand is generated whenever preferences satisfy $(N + 1)$ th-degree stochastic dominance preference.

Finally, suppose that there are two sources of future income risk (e.g., labor income and capital income) which might be correlated. How does an increase in correlation affect savings? In the setting described in section titled “Stochastic Dominance and Correlation Aversion,” increasing correlation leads to $(N + M)$ th-order deterioration. In turn, that will increase savings if preferences are

consistent with $(N + M + 1)$ th-order stochastic dominance.

Corporation with Two Headquarters. We consider here an example applying Theorem 2 with $N = 1$ and $M = 2$, but one that is not an example of a precautionary effect. Consider a risk-neutral corporation with taxable profit $\tilde{X}$ in country A and taxable profit $\tilde{Y}$ in country B . We assume that the tax schedule is identical in both countries and that $\tilde{X}$ second-order dominates $\tilde{Y}$. The tax owed on realized profit π is denoted by $t(\pi)$. The tax schedule is assumed to be increasing with a marginal tax rate that is also increasing, but at a decreasing rate. This assumption is realistic since the marginal rate is often bounded by some maximum, such as 50% of additional profit, and certainly is strictly bounded by 100%. After-tax profits can thus be written as $u(\pi) = \pi - t(\pi)$. If $t(\cdot)$ is differentiable, our assumptions about t imply that $u''(\pi) < 0$ and $u'''(\pi) > 0$. Moreover, since we should also have $t'(\pi) < 1$ for any profit level π , it follows that $u'(\pi) > 0$ as well.

Suppose now that the corporation has a new project with a pre-tax distribution of profit $\tilde{Z}$, where $\tilde{Z} > 0$ almost surely. The corporation must decide whether to locate the project in country A or in country B . The after-tax total profit of the corporation is given by $u(\pi_A) + u(\pi_B)$, where π_i denotes the realized pre-tax profit in country i , for $i = A, B$. Since $\tilde{Z}$ first-order dominates zero, it follows from Theorem 2 that $E[u(\tilde{X}) + u(\tilde{Y} + \tilde{Z})] > E[u(\tilde{X} + \tilde{Z}) + u(\tilde{Y})]$ because the valuation function u (i.e., after-tax profits) satisfies third-order stochastic dominance preference. Thus, the firm should locate the new project in country B in order to maximize its global after-tax profit.

Tempering Effects of Risk. Kimball [26] defines a key behavior consequence of temperance; namely, that an unavoidable risk will “lead an agent to reduce exposure to another (independent) risk.” From Theorem 2, we obtain a variant of Kimball’s tempering effect: an unavoidably higher level of risk in one state will lead one to reduce exposure to a second risk in that state. Here,

higher or lower “risk” is characterized via second-order stochastic dominance.

The notion of tempering effects extends to higher orders of risk. For example, Lajeri-Chaherli [27] studies the effects of background risks on precautionary savings and in doing so, examines the condition of decreasing absolute temperance. A necessary condition for this property within her expected utility framework is $u(5) > 0$, which she labels as “edginess.” By choosing $M = 2$ and $N = 3$, we can interpret edginess as implying that a decrease in one risk (via second-order stochastic dominance) helps to temper the effects of an increase in downside risk of another additive risk.

Interestingly, we can obtain a second equivalence for temperance that has nothing to do with tempering effects, by letting $N = 3$ and $M = 1$. Let $\tilde{Y}_3$ be an increase in downside risk over $\tilde{X}_3$, and let $\tilde{X}_1$ first-order dominate $\tilde{Y}_1$. The (stochastically) higher wealth in $\tilde{X}_1$ helps to mitigate the effects of the increased downside risk in $\tilde{Y}_3$. Thus, we prefer to pair $\tilde{X}_1$ together with $\tilde{Y}_3$ in our lottery preference. In the special case, where $\tilde{X}_1$ and $\tilde{Y}_1$ are both constants, we get a precautionary effect as in the section titled “Precautionary Effects.” But note how this equivalence for “temperance” does not describe any type of tempering effect. Instead, it implies that the property of temperance yields a precautionary effect in protecting against increase in downside risk of future labor income. Similarly, by choosing $M = 1$ and $N = 4$, edginess can be interpreted as implying a precautionary effect against increase in fourth-degree risk for future labor income.

Stochastic Dominance and Exponential Utility

A useful implication is that preference for the dominant lottery in Theorem 2 restricts potential forms of the utility function. Tsetlin and Winkler [28] extend this approach to a multiattribute setting. Consider a decision maker with a nondecreasing utility for wealth, $u'(x) \geq 0$. That means, for example, that \$200 is better than \$100. Consider a lottery [\$100, \$200], and suppose that we combine two such lotteries by adding outcomes.

This can be done by combining good with good and bad with bad, yielding [\$200, \$400] or by combining good with bad, yielding [\$300, \$300] which is \$300 for sure. For the choice between \$300 for sure and an uncertain outcome with a mean of \$300, a preference for combining good with bad is consistent with risk aversion: $u''(x) \leq 0$.

Now, for someone who is risk averse, we can say that \$300 is good and [\$200, \$400] is bad. Combining these two lotteries with an independent [\$100, \$200] lottery gives [[\$300, \$500], \$500] if we combine good with good and bad with bad, and [[\$400, \$600], \$400] if we combine good with bad. Up to a linear transformation, these are the same lotteries as A and B at the end of the first section (there we had [[0, 2000], 2000] and [[1000, 3000], 1000]), and combining good with bad is preferred (i.e., consistent with prudence) if $u'''(x) \geq 0$. As discussed in the section titled “Tempering Effects of Risk,” the next steps would yield temperance ($u(4)(x) \leq 0$), and then edginess ($u(5)(x) \geq 0$). Overall, preference for combining good with bad implies that $u \in \mathbb{U}_\infty$, where $\mathbb{U}_\infty = \{u | (-1)^{k-1} u^{(k)} \geq 0, k = 1, 2, \dots\}$.

Utility functions from $\mathbb{U}_\infty$ have been studied quite extensively [13, 29–32], as they are consistent with stochastic dominance of any order. Whitmore (13, p. 78) mentions that “No compelling economic rationale for this extension is apparent although it can be shown that all functions in the class exhibit nonincreasing absolute risk aversion. Moreover, $\mathbb{U}_\infty$ can be shown to contain many of the families of utility functions which are used routinely by investigators, such as the linear, exponential, logarithmic, and power families. Furthermore, one might argue that a perfectly rational economic decision maker will have preferences which undergo the smooth and systematic change with wealth level which is implied by the conditions defining $\mathbb{U}_\infty$.” The preference for combining good with bad, as opposed to combining good with good and bad with bad (Theorem 2), offers such economic rationale for $\mathbb{U}_\infty$.

Utility functions from $\mathbb{U}_\infty$ are also very tractable, since they can be characterized via Laplace transforms. Consider $u(x)$ defined on $(0, \infty)$. By Bernstein’s lemma (33, p. 439,

Theorem 1a), $u \in \mathbb{U}_\infty$ if and only if its first derivative (i.e., the marginal utility) is a Laplace transform of a (not necessarily finite) measure ψ on $[0, \infty)$: $u'(x) = \int_0^\infty e^{-rx} d\psi(r)$. Then (29, Theorem 1)

$$u \in \mathbb{U}_\infty \text{ if and only if } u(x) = u(x_0) + \int_0^\infty [(1 - e^{-r(x-x_0)})/r] d\psi(r). \quad (4)$$

By Equation (4), any utility function from $\mathbb{U}_\infty$ is a mixture (weighted average) of exponential utilities. This provides a quick way to check whether one alternative dominates another with respect to $\mathbb{U}_\infty$. These results are summarized in the theorem below, which is based on Ref. 31 (Proposition 1 and Proposition 4).

Theorem 3. *The following statements are equivalent:*

1. $\int_a^b u(x) dF(x) \geq \int_a^b u(x) dG(x)$ for all $u \in \mathbb{U}_\infty$,
2. $\int_a^b e^{-rx} dF(x) \leq \int_a^b e^{-rx} dG(x)$ for all $r \in [0, \infty)$,
3. *There exists N such that F weakly dominates G in the sense of N th-order stochastic dominance.*

By Theorem 3, exponential utility [constant absolute risk aversion (CARA)] is a main building block for ranking risky alternatives. (Note that its second condition is equivalent to ranking moment-generating functions for distributions F and G .) Even if the second condition does not hold for all r , but for a wide enough range of risk aversion levels considered to be “reasonable,” choosing F over G would be justified. This is consistent both with Kirkwood’s observation [34] that most decision analysis applications use exponential utility function and with his suggested framework of using exponential utility for sensitivity analysis with respect to risk tolerance levels. This is good news for decision analysts, since exponential utility is, arguably, the easiest to use, in particular because the certainty equivalent of a project does not depend on the presence of independent additive background risk.

SUMMARY

Probability distributions can be partially ranked via stochastic dominance (Definition 1). Within an expected utility framework, preferences are consistent with stochastic dominance of order N if the first N derivatives of the utility function alternate in sign (Theorem 1). If preferences are consistent with stochastic dominance of arbitrary high order, the utility function is a weighted average (mixture) of exponential utilities (Eq. 4).

If preferences are consistent with stochastic dominance, the choice between alternatives might be easier to determine and be somewhat independent of the particulars of the decision maker's utility function, as discussed in the section titled "Stochastic Dominance and Exponential Utility." But why should anybody's preferences satisfy stochastic dominance? Alternatively, how could we check for that?

Theorem 2 shows that the decision maker's preferences are consistent with stochastic dominance of any order if the decision maker prefers more of the attribute to less, and prefers to combine good random variables with bad ones, as opposed to combining good with good and bad with bad. This condition is similar in spirit to risk aversion and correlation aversion in the sense that it reflects an aversion to the combination of bad with bad. Given the partial ordering in Equation (2), a 50–50 gamble between two intermediate outcomes is preferred to a gamble between two extreme outcomes. Preference for combining good with bad seems intuitive in many instances, especially in the wealth or consumption context. In the assessment process, the decision maker should be presented with choices that highlight the issue of preferences for combining good lotteries with bad versus combining good with good and bad with bad.

Theorem 2 also can be used to add intuition to many other extant concepts in the literature, such as skewness preference [18] and transfer principles in income redistribution [35,36]. Furthermore, in some instances, decisions are indeed about how to allocate risks across two states (or two time periods, or two firms, or two groups of people). The

section titled "Allocating Risks" shows how such decisions can often be made independent of a particular utility function or even a particular preference function, as long as we believe that valuations are consistent with stochastic dominance criteria.

INTRODUCTION

A minimization problem is defined as

$$\min_{s \in S} f(s), \quad (1)$$

where S denotes a set of feasible configurations, and $f: S \rightarrow \mathbb{R}$, called *cost* or *objective function*, is a real valued function evaluating each configuration $s \in S$. If S is a discrete set, we are faced with combinatorial (or discrete) optimization; otherwise we refer to it as *continuous optimization*.

Combinatorial optimization, covering more or less practical problems like job shop scheduling, timetabling, graph coloring, traveling salesman problem (TSP), or vehicle routing, poses serious challenges, as most of such problems is NP-hard [1–3]. Similarly, continuous optimization of nonconvex functions of many variables makes real troubles even if the entire function is continuous and twice differentiable. Finding stationary points of f and checking definiteness of the hessian of f in these points is a time-consuming problem when the number of variables increases [4]. That is why we are looking for methods providing simple, cheap, and rather fast means for coping with Equation (1).

Such means are offered by the metaheuristics, that is, iterative processes that “guide and modify the operations of subordinate heuristics to efficiently produce high quality solutions” (5, p. 270). Simulated annealing (SA) [6,7] is an example of a metaheuristic

inspired by the process of physical annealing relying upon slowly cooling of a solid until a minimum energy configuration is attained. SA combines two strategies: random walk and iterative improvement. It can be viewed as a local search algorithm in which there are occasional “upward” moves that lead to the cost increase. In effect, the current locally optimal solution can be directed toward a global minimum.

As noted by Ingber [8], the most attractive features of SA are as follows: (i) it can process quite arbitrary objective functions and constraints; (ii) it is easy to implement; and (iii) it converges in probability to a global minimum, that is, it is possible to obtain a solution arbitrarily close to this minimum, with a probability arbitrarily close to one. Because the algorithm almost did not use any knowledge concerning the optimization problem on which it is run, it is classified—similarly as evolutionary algorithms [9]—as a “black-box” optimization algorithm. But being so universal, it is not free from disadvantages. Ingber [8] lists also its negative features, such as (i) rather low speed of convergence; (ii) difficulty with fine-tuning to specific problems; and (iii) the fact that the statistical convergence does not provide any guarantee of optimality in practical cases.

In this article, we present mathematical and implementational details concerning the SA algorithm. We start our exposition with a concise description of the Metropolis algorithm [10]. It is not only referred to as “one of top 10 algorithms with the greatest influence on the development and practice of science and engineering in the 20th century” [11] but it is also the main ingredient of the SA algorithm. Such a presentation allows also gentle introduction of basic notions from the field of Markov chains used to analyze properties of the SA. Next, in the section titled “SA Algorithm”, a basic variant of the SA algorithm is presented and its specialization to the problems from the field of combinatorial and continuous optimization are discussed, respectively, in the sections titled “SA for

Combinatorial Optimization Problems” and “SA for Continuous Optimization Problems”. Remarks on the convergence are also given here. The section titled “Other Variants of the SA Algorithm” describes further modifications of the SA algorithm. Mainly we focus here on the problems with noise or imprecise measurements of the cost function and on the problems with vector-valued cost function (i.e., multiobjective optimization). Finally, the section titled “Further Reading” concludes the article pointing to the literature devoted to the topics discussed in the previous sections.

METROPOLIS ALGORITHM

Formally, the heart of the SA is a sampling method invented by Metropolis *et al.* [10] to simulate direct draws from complicated multivariate distributions. In the literature, it is usually referred to as the *Metropolis algorithm*, and sometimes the term “M(RT)² algorithm” (referring to the initials of these authors) is used. Because of the generalization proposed by Hastings [12], we also refer to it as the Metropolis–Hastings, or M–H, algorithm. Here, we shortly review basic concepts needed to design such a sampler. A reader interested in more rigorous and fast presentation is referred, for example, to Ref. 13.

Suppose for simplicity that X is a random variable (rv) taking its values in a finite set S . In this case, S may be identified with the set $\{1, 2, \dots, n\}$. The distribution function (df) π , also called *target distribution*, which characterizes X is a vector $\pi = (\pi_1, \dots, \pi_n)$, where $\pi_i = \mathbb{P}(X = i)$ denotes the probability that X takes the value $i \in S$.

The sampling procedure can be identified with a (possibly infinite) sequence of trials $\{X_k\}$, where the probability of an outcome of a given trial depends only on the outcome of previous trial, that is, $p_{ij}(k) = \mathbb{P}(X_k = j | X_{k-1} = i)$. Such a “memoryless” sequence of trials is said to be a Markov chain [14], and $p_{ij}(k)$ are its transition probabilities. When these probabilities are independent of the trial number k , we say that $\{X_k\}$ is a homogeneous Markov chain (otherwise it is said to

be nonhomogeneous). In this case, the transition probabilities are represented by the so-called stochastic matrix $\mathbf{P} = [p_{ij}]$, that is, a real valued matrix such that

$$\sum_{j=1}^n p_{ij} = 1, \quad i = 1, \dots, n, \quad (2)$$

$$p_{i,j} \in [0, 1], \quad i, j = 1, \dots, n.$$

A nice property of such a representation is that if $a_j(k) = \mathbb{P}(X_k = j)$ stands for the probability of an outcome $j \in S$ at the k th trial, then

$$a_j(k) = \sum_{i=1}^n a_i(k-1) p_{ij}$$

$$= \sum_{i=1}^n a_i(0) p_{ij}^{(k)}, \quad k = 1, 2, \dots, \quad (3)$$

where $p_{ij}^{(k)}$ is (i, j) th entry of the matrix $\mathbf{P}^{(k)} = \mathbf{P}^k$ (i.e., $\mathbf{P}$ to the power k) representing probability of transition from i to j in k steps. Hence, a homogeneous finite Markov chain is completely determined by the pair $(\mathbf{a}(0), \mathbf{P})$, where $\mathbf{a}(0) = (a_1(0), \dots, a_n(0))$ is the initial distribution of states.

Under certain conditions (given below) on the transition probabilities, there exists a unique stationary distribution $\mathbf{s} = (s_1, \dots, s_n)$, whose components are given by

$$s_j = \lim_{k \rightarrow \infty} \mathbb{P}(X_k = j | X_0 = i)$$

$$= \lim_{k \rightarrow \infty} p_{ij}^{(k)}, \quad i = 1, \dots, n. \quad (4)$$

This equation can be rewritten in the form (here $\mathbf{1}$ stands for the column vector of ones)

$$\lim_{k \rightarrow \infty} \mathbf{P}^k = \mathbf{1} \mathbf{s} = \mathbf{S}, \quad (5)$$

that is, each row of the matrix $\mathbf{S}$ equals the row vector $\mathbf{s}$. If so, we can check that for any stochastic row vector $\mathbf{p}$ there holds

$$\lim_{k \rightarrow \infty} \mathbf{p} \mathbf{P}^k = \mathbf{p} \mathbf{S} = \mathbf{s}, \quad (6)$$

that is, if $\mathbf{s}$ is the stationary distribution of a Markov chain then, after some time, the

chain follows this distribution whatever the initial distribution $\mathbf{p}$ is.

Metropolis and his collaborators used this fact to construct a Markov chain in such a way that its stationary distribution equals a target distribution π .

Let us recall [14] that a Markov chain with transition matrix $\mathbf{P}$ is

1. irreducible, if any two states communicate with each other, that is, for any $i, j \in S$ there exists such a number $n(i, j)$ that $p_{ij}^{(n(i, j))} > 0$,
2. aperiodic, if it is not forced into some cycle of fixed length between certain states (in case of a finite chain it suffices that $p_{ii} > 0$ for some $i \in S$).

A Markov chain satisfying these two conditions has a unique stationary distribution obeying the equation $\mathbf{s} = \mathbf{s}\mathbf{P}$, that is, $\mathbf{s}$ is the left eigenvector of the matrix $\mathbf{P}$ associated with the eigenvalue $\lambda = 1$.

In the Metropolis algorithm the transition probabilities p_{ij} are defined as follows:

$$p_{ij} = \begin{cases} 0 & \text{if } j \notin N(i) \text{ and } j \neq i \\ g_{ij} a_{ij} & \text{if } j \in N(i) \text{ and } j \neq i \\ 1 - \sum_{l=1, l \neq i}^n g_{il} a_{il} & \text{if } i = j \end{cases} \quad (7)$$

Here $N(i)$ is the set of states accessible from i and g_{ij} is the so-called generation probability responsible for proposing a state j to which the chain can move in the next step. It defines an important part of the algorithm—the neighborhood structure on S as well as the size of such a neighborhood. The acceptance probability a_{ij} is the probability of accepting such a move. In case of optimization problem, the g_{ij} represents a conditional probability of moving from current solution i to a neighboring solution j ; this new solution is accepted with probability a_{ij} and rejected with probability $1 - a_{ij}$. The only problem is how to choose these probabilities.

To answer it, note that a sufficient condition for a unique stationary distribution $\mathbf{s}$ is that the detailed balance equation,

$$s_i p_{ij} = s_j p_{ji}, \quad (8)$$

holds for all i, j in S . It may be considered as a mathematical counterpart of the thermal equilibrium of a physical system. The Markov chain satisfying this condition is said to be reversible.

As we want drawing samples from the target density π , we should replace $\mathbf{s}$ by this π in the above equation. Now, if the generation matrix $\mathbf{G} = [g_{ij}]$ is irreducible (i.e., there exists such an integer k^* that all the entries of $\mathbf{G}^{k^*}$ are positive) and the next equality holds [14]

$$\frac{a_{ij}}{a_{ji}} = \frac{\pi_j g_{ji}}{\pi_i g_{ij}}, \quad (9)$$

then the Markov chain with transitions p_{ij} defined in Equation (7) is irreducible, aperiodic, and reversible. In general, to guarantee the condition (9), we define acceptance probabilities as (consult also Ref. 15 for alternative formulation)

$$a_{ij} = \varphi\left(\frac{\pi_j g_{ji}}{\pi_i g_{ij}}\right) = \varphi(\xi), \quad (10)$$

where $\varphi: [0, \infty) \rightarrow [0, 1]$ is a nondecreasing function satisfying the condition

$$\frac{\varphi(\xi)}{\varphi(1/\xi)} = \xi. \quad (11)$$

If the generation matrix is symmetric, then Equation (10) reduces to

$$a_{ij} = \varphi\left(\frac{\pi_j}{\pi_i}\right). \quad (12)$$

It is this case considered by Metropolis [10], while Equation (10) is the generalization introduced by Hastings [12]. Two examples of the mapping (Eq. 12) are frequently used

$$\begin{aligned} \varphi_1(\xi) &= \min(1, \xi), \\ \varphi_2(\xi) &= \xi/(1 + \xi). \end{aligned} \quad (13)$$

A physical system in thermal equilibrium at temperature T has its energy probabilistically distributed among all different energy states E . The law governing the distribution of the energies is the so-called Boltzmann

distribution

$$\pi_i = \frac{e^{-E(i)/(k_B T)}}{\sum_{j=1}^n e^{-E(j)/(k_B T)}} = \frac{1}{Z} e^{-E(i)/(k_B T)}, \quad (14)$$

where $E(i)$ stands for the energy of the configuration $i \in S$, k_B is the Boltzmann constant, and T denotes temperature. Choosing units where $k_B = 1$, and using φ_1 from Equation (13) we obtain standard Metropolis acceptance criterion

$$\begin{aligned} a_{ij} &= \min \left\{ 1, \exp \left[-\frac{E(j) - E(i)}{T} \right] \right\} \\ &= \min \left(1, e^{-\Delta E_{ij}/T} \right), \end{aligned} \quad (15)$$

while using φ_2 we obtain the logistic (or Barker) criterion [16]

$$a_{ij} = \frac{1}{1 + e^{\Delta E_{ij}/T}}. \quad (16)$$

Note an important difference between these criteria. The first of them accepts unconditionally any movement to the state with lowered energy, while the second accepts the states with “slightly” lowered or increased energy with the probability close to 1/2. As shown by Pescun [17], the criterion (15) is optimal among other possible choices in the sense that it rejects candidate states less often than other possible criteria. Interestingly, the matrix $\mathbf{A} = [a_{ij}]$ generated in both cases is not stochastic. And indeed it need not be a stochastic matrix—see Chapter 8 in Ref. 3 for numerical examples illustrating the way of forming the transition matrix.

Taking into account Equation (6) we see that from a physical standpoint the above procedure “simulates the thermal motion of atoms in thermal contact with a heat bath at temperature T ” [6] and allows identify ground states, that is, configuration with lowest energy in the limit of low temperature.

SA ALGORITHM

To adopt the Metropolis algorithm to the minimization problem 1, one follows these four steps:

1. Treat the set of states S as the set of admissible solutions.
2. Treat the energy E as the objective function f , and its changes ΔE_{ij} as $\Delta f_{ij} = f(j) - f(i)$.
3. Treat the temperature T as a control parameter, and develop a cooling schedule specifying how it is lowered from high to low values.
4. Define a way in which current solution $i \in S$ can be modified to generate a next (neighboring) solution j . The neighbors of a given solution correspond to the set $N(i)$ of states accessible from a given state i .

The minimization procedure can be summarized as follows:

1. **Initialization:** Set the counter $k \leftarrow 0$, choose initial temperature T_k , and an initial solution $i_k \in S$. Set $f_k \leftarrow f(i_k)$, $i_{\text{best}} \leftarrow i_k$, $f_{\text{best}} \leftarrow f_k$.
2. **while** not done
 - (2a) **repeat** sufficient number of times
 - (2a-1) choose randomly (with probability $g_{i_k j}$) a neighbor $j \in N(i_k)$ and evaluate it, $f_j \leftarrow f(j)$
 - (2a-2) if $r < a_{i_k j}(T_k)$, where r is a random number drawn from the uniform distribution $U(0, 1)$, then $i_k \leftarrow j$ else do not change i_k
 - (2a-3) if $f_j < f_{\text{best}}$ then set $i_{\text{best}} \leftarrow j$, $f_{\text{best}} \leftarrow f_j$
 - (2b) lower the temperature, $T_{k+1} \leftarrow c(T_k)$
 - (2c) $k \leftarrow k + 1$
3. **return** $i_{\text{end}}, f_{\text{end}}$

Note that the “pure” SA algorithm does not keep track of the best solution found so far, that is, it does not use the variables i_{best} and f_{best} ; however, it is a standard practice used when implementing optimization algorithm allowing to focus on substantial improvements only.

To use the SA algorithm the next ingredients must be detailed: a neighborhood

structure for implementing step (2a-1), a transition mechanism for implementing step (2a-2) and a cooling schedule requested in step (2b). Obviously a proper, that is, concise and easy-to-manage representation of the entire problem must be established first.

Also, it would be nice to have recipes allowing to choose initial temperature and initial configuration. The first of these problems is very subtle, and some hints on how to choose T_0 can be found, for example, in Section 1.7 of Ref. 1. The initial configuration i_0 is usually chosen randomly from S . However, a good initial configuration results in faster convergence. Thus it is possible, for instance, to run a simple heuristic (e.g., hill-climbing algorithm) to find a tentative configuration and use it then as i_0 in the algorithm.

To fully specify the algorithm, we also need to know the number of repetitions of the inner and outer loops. The **repeat** loop—obeying steps (2a-1)–(2a-3) implement the Metropolis algorithm. The number of repetitions of this loop at fixed temperature depends heavily on the cooling schedule realized in step (2b). This schedule also affects a stopping criterion. Formally, the algorithm stops when the temperature T_k is close to zero, although more practical criteria are often used.

We discuss these topics in the following sections. Although SA is a general-purpose algorithm, some of its implementational details depend on a problem representation. That is why we distinguish between the variants designed for combinatorial and continuous optimization.

A reader interested in further details concerning computer implementation is referred, for example, to Section 10.9 in Ref. 18. Its first part describes a program for solving the TSP with possibly additional constraints, and in the second part of this section continuous minimization is considered.

SA FOR COMBINATORIAL OPTIMIZATION PROBLEMS

Specialization of the SA Algorithm

Neighborhood Structure. Formally, the neighborhood structure is defined by a func-

tion $N: S \rightarrow 2^S$ that assigns to every admissible solution $i \in S$ a set of neighbors $N(i) \subseteq S$, that is, a set of “slight” modifications of the entire solution i [2].

To be illustrative, consider a symmetric TSP problem with n cities. Typically, the cities are labeled by subsequent integers $1, 2, \dots, n$, and j th city has coordinates (x_j, y_j) . A configuration i is a permutation $i_{(1)} i_{(2)} \dots i_{(n)}$ of the set $\{1, \dots, n\}$ interpreted as the order in which the cities are visited. Thus assuming that the salesperson starts from a fixed city, the space S consists of $(n-1)!$ permutations representing possible tours. Note that such a representation although simple has one disadvantage: each tour is represented by n different permutations. For instance, if $n = 8$ then, for example, $\{1, 2, 3, 4, 5, 6, 7, 8\}$ and $\{8, 1, 2, 3, 4, 5, 6, 7\}$ represent the same tour. A neighbor of a tour i can be obtained by using three different operations explained in Fig. 1. Two of them were invented by Lin [19], while the third is an operator used in evolutionary computations.

An important property which the neighborhood structure must possess is that for any two states $i_s, i_f \in S$ there exists a finite sequence of $K \geq 2$ states $j_1, \dots, j_K$ such that $j_k \in N(j_{k-1}), k = 2, \dots, K$, and $i_s = j_1, i_f = j_K$. Such a sequence is referred to as the *path*, and the neighborhood structure with which any two states are joined by a path is said to be well defined. Surely, the neighborhoods induced by the operators from Fig. 1 are well defined. Detailed discussion on how to define effective neighborhood structures can be found, for example, in Refs 2 and 3.

Tuning Parameters of the Algorithm. With the neighborhood structure, the generation probability is defined in standard SA as

$$g_{ij} = \begin{cases} \frac{1}{|N(i)|} & \text{if } j \in N(i) \\ 0 & \text{otherwise} \end{cases} \quad (17)$$

where $|N(i)|$ is the cardinality of the set $N(i)$, and the acceptance probability is defined as in Equation (15). In other words, all the neighbors are of equal importance.

The temperature T_k is lowered from some initial value T_0 until the final value

Figure 1. Operators for generating neighbors of a tour in a TSP: (a) original tour $i = \{1, 2, 3, 4, 5, 6, 7, 8\}$, (b) 2-change, or inversion: reverses the order in randomly chosen subtour $3, 4, 5, 6$, that is, $i' = \{1, 2, 6, 5, 4, 3, 7, 8\}$, (c) translation: places randomly chosen subtour, for example, $3, 4, 5, 6$ after randomly chosen city, for example, city no. 1: $i'' = \{1, 3, 4, 5, 6, 2, 7, 8\}$, (d) switching: interchanges the cities from two randomly chosen positions in the tour, here fourth and seventh positions, that is, $i''' = \{1, 2, 3, 7, 5, 6, 4, 8\}$.

T_f is reached. The problem of choosing proper initial and final values as well as the problem of how fast this T_k should be lowered requires deeper reflection, and, frequently, trial-and-error experiments. Detailed discussion of these topics can be found, for example in Refs 20 and 21. Some suggestions on how to choose the value of T_0 are given in Section 1.7 in Ref. 1.

The most frequently used cooling schedules are geometric,

$$\begin{aligned} c_1(T_k) &= \alpha T_k = T_0 \alpha^k, \quad \alpha \in [0.8, 0.99], \\ k &= 1, 2, \dots, \end{aligned} \quad (18)$$

or hyperbolic schedule,

$$c_2(T_k) = \frac{T_k}{1 + \beta T_k}, \quad \beta \approx 0, k = 1, 2, \dots \quad (19)$$

Although the geometric schedule does not, in general, guarantee convergence to the minimum, it is popular because it allows convergence in reasonable time. Other cooling schedules are discussed and reviewed, for example, in Refs 1, 22, and 23.

It is suggested—see Ref. 1, Section 1.7 of Ref. 18—that each new value of T_k in Equation (18) should be constant for $100n$ reconfigurations, or for $12n$ successful reconfigurations, whichever comes first. Here n stands for the number of parameters (degrees of freedom) of the problem to be solved.

The **while**-loop (2) in the SA algorithm stops after few (say three to five) successive temperature stages without any acceptance.

Convergence of the Algorithm

Under certain conditions, the SA algorithm converges in probability to the set of optimal

solutions $S^* \subseteq S$, that is,

$$\lim_{k \rightarrow \infty} \mathbb{P}(X_k \in S^*) = 1, \quad (20)$$

where X_k denotes the random variable being the outcome of k th iteration of the algorithm. To prove this fact, we can view the SA algorithm as a sequence of infinitely long homogeneous Markov chains, or as an inhomogeneous Markov chain with transition probabilities depending on current temperature T_k (and thus on iteration number k). The second approach is much more complicated, and hence we briefly sketch the first one only. Detailed discussion of this subject can be found, for example, in Chapter 8 of Ref. 3.

In the first (rather unrealistic) case, these “certain conditions” are such that the Markov chain controlled by the transition probability matrix $\mathbf{P}(T_k)$ is irreducible and aperiodic for a fixed value of T_k . For instance, if the neighbor structure N is well defined, the generation probabilities g_{ij} are given by Equation (17) and the acceptance probabilities a_{ij} by Equation (15), then the matrix $\mathbf{P}$ with entries (7) is regular, and such that $p_{jj} > 0$ for at least one $j \in S$ (see, e.g., Theorem 8.4 in Ref. 3). Thus, there exists the unique stationary distribution $\pi(T_k)$ with the components (cf. Theorem 8.5 in Ref. 3)

$$\pi_i(T_k) = \frac{e^{-f(i)/T_k}}{\sum_{j \in S} e^{-f(j)/T_k}} = \frac{e^{-f(i)/T_k}}{Z(T_k)}. \quad (21)$$

Denoting $f^* = \min_{i \in S} f(i)$, these components may be rewritten in the form

$$\begin{aligned} \pi_i(T_k) &= \frac{e^{-f(i)/T_k}}{Z(T_k)} \cdot \frac{e^{f^*/T_k}}{e^{f^*/T_k}} \\ &= \frac{\exp[-(f(i) - f^*)/T_k]}{\sum_{j \in S} \exp[-(f(j) - f^*)/T_k]}. \end{aligned} \quad (22)$$

Defining $\delta = \min_{j \in S \setminus S^*} f(j) - f^*$ and observing that the denominator of this last expression is greater than one, we can write (cf. Lemma 8.2 in Ref. 3)

$$\pi_i(T_k) \leq \exp\left(-\frac{\delta}{T_k}\right), \quad (23)$$

which implies that

$$\lim_{T_k \rightarrow 0} \pi_i(T_k) = \begin{cases} 0 & \text{if } i \in S \setminus S^* \\ \frac{1}{|S^*|} & \text{if } i \in S^* \end{cases} \quad (24)$$

According to Lemma 8.4 in Ref. 3 the Equation (24) holds also for nonsymmetric generation probabilities g_{ij} .

Thus, the SA algorithm converges to a global minimum if for each value of $T_k, k = 0, 1, \dots$, the corresponding Markov chain is infinitely long and the sequence of the temperatures T_k converges to zero as $k \rightarrow \infty$.

Geman and Geman [24] is perhaps the most popular reference establishing conditions on the cooling schedule for formal convergence of a variant of SA algorithm designed for image restoration problem (consult Section 8.6 in Ref. 25 for a deeper discussion). More general result, formulated under nonhomogeneous Markov chain assumption, states that (consult [26]) the SA algorithm converges if and only if $\lim_{k \rightarrow \infty} T_k = 0$ and

$$\sum_{k=1}^{\infty} \exp(-h^*/T_k) = \infty, \quad (25)$$

where h^* is the smallest number such that every state $i \in S$ communicates with S^* at height h^* . Recall from Ref. 26 that a state $i \in S$ communicates with S^* at height h if there exists a path $j_1, \dots, j_K$ in S such that $j_1 = i$ and $j_K \in S^*, K > 1$, and such that $f(j_k) \leq f(j_1) + h$ for all $k = 2, \dots, K$. This result shows that certain annealing schedules guarantee convergence to S^* . Particularly, we can use a logarithmic schedule

$$c_3(T_k) = \frac{d}{\log(1+k)}, \quad (26)$$

where d is a positive constant such that $d \geq h^*$. The only problem relies upon estimation of the value h^* . Gidas [27] gives a similar condition together with a discussion on how to choose d .

Note also that for continuous state spaces there are results in the form of stochastic differential equations—the reader is referred to section titled “SA with noisy cost function” for further details.

Some Extensions

An intriguing generalization of the Boltzmann distribution (14) is obtained by considering generalized entropy (consult Ref. 28 for a quick introduction)

$$\text{Ent}_q = k \frac{1 - \sum_{i \in S} p_i^q}{q - 1}, \quad q \in \mathbb{R}. \quad (27)$$

The principle of maximum entropy constraining the energy to average value T leads to the distribution

$$\begin{aligned} p_i &= \frac{[1 - \beta(1 - q)E(i)]^{1/(1-q)}}{\sum_{j \in S} [1 - \beta(1 - q)E(j)]^{1/(1-q)}} \\ &= \frac{[1 - \beta(1 - q)E(i)]^{1/(1-q)}}{Z_q}, \end{aligned} \quad (28)$$

where $\beta = 1/(k_B T)$ is the “inverse temperature”. Particularly, in the $q \rightarrow 1$ limit we recover the Boltzmann distribution (14). The distribution (28) generalizes large families of standard distributions like Lévy α -stable distributions L_α [29], and Student’s t - and r -distributions [30]. The paper [29] provides a simple and efficient procedure for generating deviates from such a distribution. It is a generalization of Box–Müller method for generating Gaussian deviates.

Penna [31] was the first who proposed using such a distribution in solving the TSP problem. Here the Metropolis criterion (15) generalizes to

$$a_{ij}(q; T) = \min \left\{ 1, [1 - (1 - q)\Delta E_{ij}/T]^{1/(1-q)} \right\}, \quad (29)$$

and obviously it approaches Equation (15) in the $q \rightarrow 1$ limit. Numerical experiments reported in Ref. 31 show that for $q < 0$, the number of annealing steps is considerably smaller than in the classical SA algorithm.

Further modification of Equation (29) was proposed by Franz and Hoffmann [32].

In conclusion of this section, let us mention an important problem of adapting the size of the neighborhood. As noted in Ref. 33 “limitation of SA with a fixed neighborhood size is its

inability to perform search at different scales in different stages of search”. This problem is naturally solved in the case of continuous optimization (described in the next section), but in combinatorial optimization it is rarely considered, although varying the neighborhood size improves search abilities (see, e.g., the VNS algorithm described in Refs 2 and 5). The papers [33,34] are attempts to solve this problem efficiently.

SA FOR CONTINUOUS OPTIMIZATION PROBLEMS

At present, we assume that $S \subset \mathbb{R}^n$, that is, we search for such a vector $\mathbf{x} = (x_1, \dots, x_n)$, which minimizes a real valued function f of n -variables.

The simple distribution (17) is not sufficient in this case. Chib and Grindberg [13] mention five methods of drawing candidates to implement the Metropolis algorithm and they conclude that precise answer to the question how these choices should be made is far from complete. The most popular method relies upon generating the candidate $\mathbf{y}$, given current solution $\mathbf{x}$, according to the equation

$$\mathbf{y} = \mathbf{x} + \mathbf{z}, \quad (30)$$

where $\mathbf{z}$ is called the *increment rv*, or simply, a disturbance, and follows a multivariate density $p(\mathbf{z})$. Now the generation density is written $g(\mathbf{x}, \mathbf{y})$ and $g(\mathbf{x}, \mathbf{y}) = p(\mathbf{y} - \mathbf{x})$.

Below, we briefly review the most popular variants of the SA algorithm devoted to unconstrained optimization problems. Note, however, that using random walk (30) we can go beyond the set S , hence some “repair” strategies must be eventually designed to prevent such a situation.

An extensive review of other variants of SA can be found, for example, in Chapters 1 and 5 of Ref. 1 and in Ref. 35.

Classical Simulated Annealing

In the field of evolution strategies, we use the term *mutation probability* to name the pdf p . Symmetric multivariate Gaussian pdf is a most natural candidate for generating random vectors $\mathbf{z}$. It perfectly fits to the

assumptions of the Metropolis algorithm and to the three postulates formulated by Beyer and Schwefel in Ref. 9. These postulates are as follows:

1. *Reachability*: Any state $\mathbf{x} \in S$ should be reachable from any other state $\mathbf{y} \in S$ in finite time.
2. *Scalability*: The length of search step (mutation strength) should be tunable in order to adapt to the properties of the fitness landscape.
3. *Absence of Biases*: The distribution $p(\mathbf{z})$ should be chosen according to the maximum entropy principle. If $S = \mathbb{R}^n$ this requirement leads naturally to the normal distribution, and if $S = \mathbb{Z}^n$ —to the geometrical distribution.

Assuming that the standard deviation σ , referred to as the *step size*, is proportional to the temperature T_k at iteration k , that is, $\sigma = \sqrt{T_k}$, the density function used to generate isotropic disturbances takes the form

$$p_k(\mathbf{z}) = \frac{1}{(\pi T_k)^{n/2}} \exp\left(-\frac{\|\mathbf{z}\|^2}{2T_k}\right). \quad (31)$$

Such a choice allows vigorous search of S with large steps in high temperatures, and very careful improvements of the solution realized with small steps in lower temperatures. In other words, the size of the neighborhood decreases with time steps. Note also that it is easy to generate variate $\mathbf{z}$: all its components have the form $\sqrt{T_k} \cdot N(0, 1)$, where $N(0, 1)$ stands for the standard Gaussian random number.

Geman and Geman [24] proved that the SA with the Metropolis acceptance criterion and Gaussian disturbances converges to the global minimum if and only if the temperature T_k in k th iteration is inversely proportional to the logarithmic function of iterations number, given a sufficiently high initial temperature T_0 , that is,

$$T_k = \frac{T_0}{\log(1+k)}. \quad (32)$$

A simple heuristic justification of this fact can be found in Refs 8 and 36, and a rigorous

treatment of this topic is provided by Gidas [27]. Other studies on the convergence of such an algorithm are reviewed in Section 4 of Ref. 35.

Fast Simulated Annealing

The random walk employed to generate candidate solutions is an important factor influencing the rate of convergence of SA. If it allows reasonable exploration, supported by a smart exploitation of “most interesting” distant regions of the search space, then the chance of fast identification of the global optimum grows radically.

This observation inspired Szu and Hartley [36] to replace multinormal Gaussian disturbance occurring in Equation (30) by isotropic multivariate Cauchy disturbance with the pdf

$$p_k(\mathbf{z}) = \frac{\Gamma\left(\frac{n+1}{2}\right)}{\pi^{\frac{n+1}{2}}} \frac{T_k}{(\|\mathbf{z}\|^2 + T_k^2)^{\frac{n+1}{2}}}. \quad (33)$$

Under such a setting, and the choice of the logistic acceptance criterion (16), the cooling schedule takes the form

$$T_k = \frac{T_0}{1+k}, \quad (34)$$

that is, it is inversely linear in the number of iterations.

Important feature of the multivariate Cauchy distribution $C(0, T_k)$ is that it realizes occasionally long jumps among essentially local sampling over the search space. This is in contrast with local sampling controlled by multinormal distribution; here the expected distance between the current point $\mathbf{x}_k$ and its neighbor $\mathbf{y}_{k+1}$ equals $\sigma_k \sqrt{n}$.

Cauchy distribution is a special case of α -stable Lévy distribution L_α (mentioned earlier), where $\alpha \in (0, 2]$ is a parameter. Particularly, $\alpha = 2$ corresponds to Gaussian distribution and $\alpha = 1$ to Cauchy distribution. The tails of such a distribution vanish as $x^{-(1+\alpha)}$ what results in the variance divergence when $\alpha \neq 2$ and—finally—in much larger jumps called, also, *Lévy flights*. Further information on this family can be found in Ref. 37 (an interested reader can visit Nolan’s web page <http://academic2.american.edu/~jhnolan/>).

edu/~jpnolan/ to find links to many papers on this subject as well as some software). Other good source of recipes showing how to generate random vectors with such distributions is Ref. 38.

Very Fast Simulated Annealing

Further quickening of the cooling process can be gained by tuning search intensity along each dimension individually. As the step size should be proportional to the temperature T_k , the requirement of individual tuning implies that the temperature varies along each dimension individually. More precisely, i th component z_i of the vector $\mathbf{z}$ is generated according to the density [8]

$$p_k(z_i) = [\kappa (|z_i| + T_{k,i}) \log(1 + 1/T_{k,i})]^{-1}, \quad (35)$$

where $T_{k,i}$ is the temperature in dimension i at time k , and κ is a normalizing constant. The joint pdf $p_k(\mathbf{z})$ is the product of all the densities $p_k(z_i)$, $i = 1, \dots, n$. Contrary to the Gaussian and Cauchy distributions already considered, this pdf is anisotropic. In this case, we obtain exponential cooling schedule

$$T_{k,i} = T_{0,i} \exp(-b_i k^{1/n}), \quad (36)$$

where k, b_i , and $T_{0,i}$ are appropriate constants. Further details of this algorithm—now called *adaptive simulated annealing* (ASA)—can be found at Ingber’s web page <http://www.ingber.com/#ASA>. Apart from scientific papers, the source code in C language can be downloaded from this page.

The method leading to the ASA algorithm was further developed by Yao [39] who proposed to replace the pdf (35) by

$$p_k(z_i) = [\kappa (|z_i| + 1/\log(1/T_{k,i})) \log(1 + \log(1/T_{k,i}))]^{-1}. \quad (37)$$

This time the cooling schedule takes the form

$$T_{k,i} = T_{0,i} \exp\left[-\exp(b_i k^{1/n})\right]. \quad (38)$$

Although these results sound very promising, it should be noted that the heuristic proof used in Ref. 36 is based on the assumption of generating and not visiting any state infinitely often in time—consult [39] for a deeper discussion of this topic.

Generalized Simulated Annealing

Tsallis distribution, called also *q-Gaussian distribution* in Ref. 29, and discussed in the section titled “Some Extensions” can be used for solving continuous optimization problems also. Tsallis and Stariolo [40] are the first who proposed such an algorithm. Its convergence is studied by Nishimoro and Inoue in Ref. 41.

OTHER VARIANTS OF THE SA ALGORITHM

Up to this moment, it was assumed that the cost of any configuration i (if S is discrete) or $\mathbf{x}$ (if $S \subset \mathbb{R}^n$) can be univocally measured and expressed as a single scalar. In this section we relax this assumption. Allowing imprecise measurements we obtain so-called stochastic annealing, and while allowing vector valuation of f we are faced with multiobjective optimization.

SA with Noisy Cost Function

Assume that the evaluation of the cost function is imprecise or is disturbed by random noise. The second case is easier to process and can be treated as an approximation of the former one. In general, there are two ways to cope with such a problem. The first adapts SA to the requirement of imprecise measurements, while the second combines it with the algorithms of stochastic optimization. Brief review of these approaches can be found in Ref. 42 and Section 8.2.2 in Ref. 25, while the second approach, elaborated, among others, by Gelfand and Mitter [43], is described in Section 8.4 and 8.6 in Ref. 25 and in Section 3 in Ref. 35.

Let $\tilde{f}(\mathbf{x})$ denote the evaluation of the true and unknown value $f(\mathbf{x})$ disturbed by a Gaussian noise, that is, $\tilde{f}(\mathbf{x}) = f(\mathbf{x}) + \epsilon$, where $\epsilon \sim N(0, \sigma^2)$. Obviously, the observed difference $\Delta \tilde{f}_{\mathbf{xy}} = \tilde{f}(\mathbf{x}) - \tilde{f}(\mathbf{y})$ is also Gaussian rv $N(\delta_{\mathbf{xy}}, \tilde{\sigma}^2)$ where $\delta_{\mathbf{xy}} = f(\mathbf{x}) - f(\mathbf{y})$ is the

true difference, and $\tilde{\sigma}^2 = 2\sigma^2$. The true value of $\delta_{\mathbf{xy}}$ can be estimated by averaging its multiple observations. Denoting j th such an observation as $\Delta \tilde{f}_{\mathbf{xy}}^{(j)}$, we estimate $\delta_{\mathbf{xy}}$ as

$$\hat{\delta}_{\mathbf{xy}}^m = \frac{1}{m} \sum_{j=1}^m \Delta \tilde{f}_{\mathbf{xy}}^{(j)}. \quad (39)$$

Now the only problem is to estimate the acceptance probability $a(\hat{\delta}_{\mathbf{xy}}^m)$. It was observed in Ref. 44 that the cumulative normal distribution with appropriately chosen variance looks very similar to the logistic acceptance criterion (16). This allows to derive a correlation between the number of samples m and the temperature T :

$$T \approx \sqrt{\frac{8m}{\pi \tilde{\sigma}}}.$$

Assuming further the deterministic rule to accept the candidate solution if $\hat{\delta}_{\mathbf{xy}}^m \leq 0$, we obtain so-called stochastic simulation algorithm [44]. A number of drawbacks of this approach was noted in Ref. 42, where a more efficient variant with effective sampling mechanism was proposed.

The second approach can be summarized as a discretized version of the Langevin equation [35]

$$\mathbf{x}_{k+1} = \mathbf{x}_k - a_k \tilde{G}_k(\mathbf{x}_k) + b_k \mathbf{w}_k, \quad (40)$$

where $\tilde{G}_k(\mathbf{x}_k)$ represents a direct (noisy) gradient $\partial f / \partial \mathbf{x}$ if f is a function of class C^2 or its approximation estimated from noisy measurements. $\{a_k\}$ is a sequence of positive step sizes, $\{b_k\}$ is a sequence of “temperatures” such that $\lim_{k \rightarrow \infty} b_k = 0$, and $\{\mathbf{w}_k\}$ is a sequence of independent, identically distributed Gaussian vectors $N(\mathbf{0}, \mathbf{I}_n)$. Adding random disturbance $b_k \mathbf{w}_k$ simulates the decision step of SA algorithm, where an upward move is sometimes accepted in the hope of leaving a local minimum attained by the algorithm.

Generally the algorithm slowly converges to the global minimum, that is, as $1 / \log \log k$. Further details about this approach can be found in the original paper [43] or in Section 8.4 of Ref. 25, while Section 8.6 clarifies the convergence theory of such an algorithm.

SA for Multiobjective Optimization

In multiobjective optimization, each configuration $\mathbf{x}$ is evaluated using few, say $v > 1$, different criteria, that is, $f(\mathbf{x})$ is now a vector consisting of v values $[f_1(\mathbf{x}), \dots, f_v(\mathbf{x})]$.

A simplest way of comparing different configurations is to associate a weight $w_j \geq 0, j = 1, \dots, v$ with each criterion and define a single objective function $f'(\mathbf{x}) = \sum_{j=1}^v w_j f_j(\mathbf{x})$. Such a procedure is rather trivial and frequently controversial: there is no unique recipe how to choose the weights in advance.

A more serious approach makes use of the notion of nondominance, or min-dominance in our case. Namely, we say that a configuration $\mathbf{x}$ min-dominates other configuration $\mathbf{y}$ (or, that $\mathbf{y}$ is min-dominated by $\mathbf{x}$) only if $f_j(\mathbf{x}) \leq f_j(\mathbf{y}), j = 1, \dots, v$, and $f_{j^*}(\mathbf{x}) < f_{j^*}(\mathbf{y})$ for at least one $1 \leq j^* \leq v$.

Now the real challenge in extending SA to handle multiple objectives lies in determining how to compute the probability of accepting an individual $\mathbf{y}$ min-dominated by current configuration $\mathbf{x}$. A simple solution is to consider the difference in the number of criteria that they min-dominate configuration $\mathbf{y}$. Particularly, in Ref. 45 so-called amount of domination was proposed. Apart from the number of poorly satisfied criteria, this measure takes into account relative differences between the evaluations of these criteria.

A number of specific approaches is reviewed in Section 10.2 in Refs 45–47.

Parallelization of the SA Algorithm

As the computing time is a critical factor in many disciplines, parallel versions of the algorithm were proposed. Two main approaches to the parallelization are proposed: (i) using P elementary processors P Markov chains are executed and (ii) only several states of the same Markov chain are executed on a single processor. These approaches are briefly characterized in Section 1.4 in Ref. 1, and the book by Azencott [48] is a good source of information on this subject.

Parallel SA can exploit functional parallelism: the use of multiple processors to evaluate different phases of a single move,

implementing several Markov chain computations in parallel [48], carrying out parallel computations for several states of the same Markov chain [1]. The data parallelism in SA is employed by the use of different processors or group of processors that propose and evaluate moves by multiple independent runs [11].

FURTHER READING

There is a vast literature devoted to the theory and application of SA. Concluding the article, we propose some guide to the literature.

The book [14] presents rigorously important facts from the field of Markov chains while the paper [13] offers readable introduction to the M–H algorithm.

Chapter 8 in Ref. 25 gives a short and detailed description of main directions developed within the annealing algorithms. Many interesting and practical information on SA and its applications can be found in Chapter 1 in Ref. 1, while new variants of this algorithm (like simulated diffusion or microcanonic annealing) are described in Chapter 5. The book also describes other metaheuristic and fast introduction to this field can be found in the paper [5]. Formal framework for local search algorithms and easy accessible considerations on the asymptotic convergence of SA is provided by the book [3]. Another variant of SA termed *quantum annealing*, that is, an optimization method inspired by a process of quantum fluctuations, and its relation to SA is discussed in the book [49].

Section 4 of Ref. 8 contain a review of various applications of SA in quite complex problems, while in Section 1 of this paper, advantages and disadvantages of SA are given. In papers [50,51], the performance of SA on three problems: graph partitioning, graph coloring, and numbers partitioning, is discussed. The general conclusion is such that the performance of SA is mixed; in some problems it outperforms the best-known tailored heuristics, and in other cases specialized heuristics performs better. In our opinion, this is not a pessimistic conclusion. It rather confirms the “no free lunch”

theorem presented in Ref. 52. According to this theorem, if algorithm *A* outperforms algorithm *B* on some cost functions, then broadly speaking there must exist exactly as many other functions where *B* outperforms *A*. The study [53] examines the performance of SA on another combinatorial problem: maximum matching problem.

Lastly, let us note that using stable distributions when generating neighbors of a given configurations opens new possibilities for designing efficient metaheuristics. Exhaustive bibliography concerning theory and application of Tsallis statistics (including SA) can be downloaded from <http://tsallis.cat.cbpf.br/biblio.htm>.

SIMULATION OPTIMIZATION IN RISK MANAGEMENT

MARCO BETTER
FRED GLOVER
OptTek Systems, Inc., Boulder,
Colorado

INTRODUCTION

Without uncertainty there is no risk. However, very few, if any, real-world situations are risk free. In the world of deterministic optimization, we often choose to “ignore” uncertainty in a given situation in order to come up with a unique and objective solution to a problem. But in situations where uncertainty is at the core of the problem, as it is in those that involve risk management, a different strategy is required.

The field of optimization offers various approaches to cope with uncertainty. In this context, the exact values that the parameters (e.g., the data) of the optimization problem will have are not known with absolute certainty, but may vary to a greater or lesser extent depending on the nature of the factors they represent. In other words, there may be many possible “realizations” of the parameters, each of which is called a *scenario*.

The following sections titled “Scenario Optimization” and “Robust Optimization” briefly describe traditional scenario-based approaches to optimization, such as *scenario optimization* and *robust optimization*. The section titled “Simulation Optimization” then delves in greater detail into a recently emerging approach called *simulation optimization* that is having a profound impact on risk management.

SCENARIO OPTIMIZATION

Dembo [1] offers an approach to solving stochastic programs based on a method for

solving deterministic scenario subproblems (SPs) and combining the optimal scenario solutions into a single feasible decision.

Imagine a situation in which we want to minimize the cost of producing a set J of finished goods. Each good j ($j = 1, \dots, n$) has a per-unit production cost c_j associated with it, as well as an associated utilization rate a_{ij} of resources for each finished good. In addition, the plant that produces the goods has a limited amount of each resource i ($i = 1, \dots, m$), denoted as b_i . We can formulate a deterministic mathematical program for a single scenario s (SP) as follows:

SP:

$$z^s = \min \sum_{j=1}^n c_j^s x_j \quad (1)$$

Subject to:

$$\sum_{j=1}^n a_{ij}^s x_j = b_i^s \quad \text{for } i = 1, \dots, m \quad (2)$$

$$x_j \geq 0 \quad \text{for } j = 1, \dots, n, \quad (3)$$

where c^s , a^s , and b^s , respectively, represent the realization of the cost coefficient, the resource utilization, and the resource availability data under scenario s . Consider, for example, a company that manufactures a certain type of Maple door. Depending on the weather in the region where the wood for the doors is obtained, the costs of raw materials and transportation will vary. The company is also considering whether to expand production capacity at the facility where doors are manufactured, so that a total of six scenarios must be considered. The six possible scenarios and associated parameters for Maple doors are shown in Table 1.

Therefore, model SP needs to be solved once for each of the six scenarios.

The scenario optimization approach can be summarized in two steps:

Table 1. Possible Scenarios for Maple Doors

Scenario	Capacity	$P(C)$ (%)	Weather	$P(W)$ (%)	P (Scenario)	Cost, c_j	Utilization, a_{ij}	Availability, b_j
1	Current	50	Dry	33	1/6	Low	High	Low
2			Normal	33	1/6	Medium	Low	Low
3			Wet	33	1/6	High	Low	Low
4	Expanded	50	Dry	33	1/6	Low	High	High
5			Normal	33	1/6	Medium	Low	High
6			Wet	33	1/6	High	Low	High

1. Compute the optimal solution to each deterministic SP.
2. Solve a tracking model to find a single, feasible decision for all scenarios.

The key aspect of scenario optimization is the function of the tracking model in step 2. For illustration we introduce a simple form of tracking model. Let p^s denote the estimated probability for the occurrence of scenario s . Then, a simple tracking model for our problem can be formulated as follows:

$$\begin{aligned} \text{Minimize } & \sum_s p^s \left(\sum_j c_j^s x_j - z^s \right)^2 \\ & + \sum_s p^s \left(\sum_{ij} a_{ij}^s x_j - b_i^s \right)^2 \end{aligned} \quad (4)$$

$$\text{Subject to : } x_j \geq 0 \quad \text{for } j = 1, \dots, n. \quad (5)$$

The purpose of this tracking model is to find a solution that is feasible under all the scenarios, and penalize solutions that differ greatly from the optimal solution under each scenario. The two terms in the objective function are squared to ensure nonnegativity. More sophisticated tracking models can be used for various different purposes. In risk management, for instance, we may select a tracking model that is designed to penalize performance below a certain target level.

ROBUST OPTIMIZATION

Robust optimization may be used when the parameters of the optimization problem are known only within a finite set of values. The robust optimization framework gets its

name because it seeks to identify a robust decision—that is, a solution that performs well across many possible scenarios.

In order to measure the robustness of a given solution, different criteria may be used. Kouvelis and Yu identify three criteria: (i) absolute robustness, (ii) robust deviation, and (iii) relative robustness. We illustrate the meaning and relevance of these criteria, by describing the robust optimization approach described in Ref. 2.

Consider an optimization problem where the objective is to minimize a certain performance measure such as cost. Let S denote the set of possible data scenarios over the planning horizon of interest. Also, let X denote the set of decision variables and P the set of input parameters of our decision model. Correspondingly, we let P^s identify the value of the parameters belonging to scenario s and let F^s identify the set of feasible solutions to scenario s . The optimal solution to a specific scenario s is then

$$z^s = f(X_s^*, P^s) = \min_{X \in F^s} f(X, P^s). \quad (6)$$

We assume here that f is convex. The first criterion, absolute robustness, also known as *worst-case optimization*, seeks to find a solution that is feasible for all possible scenarios and optimal for the worst possible scenario. In other words, in a situation where the goal is to minimize the cost, the optimization procedure will seek the robust solution, z^R , that minimizes the cost of the maximum-cost scenario. We can formulate this as an objective function of the form

$$z^R = \min \left\{ \max_{s \in S} f(X, P^s) \right\}. \quad (7)$$

The second criterion, robust deviation, is the one that minimizes the largest deviation from optimality. In other words, we seek to minimize the worst-case deviation that separates the robust solution from the optimal solution to each scenario. The third criterion, relative robustness, is similar to the second, but instead of a direct deviation measure, we use a relative deviation measure with respect to optimality. Suppose, for convenience, we reformulate the SP introduced in the previous section as follows (based on Ref. 2, pp. 26–29):

$$z^s = \min c^s x \quad (8)$$

$$\text{Subject to : } A^s x = b^s \quad (9)$$

$$x \geq 0. \quad (10)$$

Then, the robust deviation problem would be formulated as

$$\text{Minimize } y \quad (11)$$

$$\text{Subject to : } c^s x \leq y + z^s \quad (12)$$

$$A^s x = b^s \quad (13)$$

$$x \geq 0. \quad (14)$$

Variations to this basic framework have been proposed in Ref. 3 to capture the risk-averse nature of decision makers, by introducing higher moments of the distribution of z^s in the optimization model, and implementing weights as penalty factors for infeasibility of the robust solution with respect to certain scenarios.

SIMULATION OPTIMIZATION

Until quite recently, the methods available for finding optimal decisions have been unable to effectively handle the complexities and uncertainties posed by many real-world situations of the form treated by simulation. The areas of scenario optimization and robust optimization described in the previous sections attempt to deal with some of these, but the modeling framework limits the range of situations that can be tackled with such technology.

The complexities and uncertainties that render real-world systems mathematically intractable are the primary reason that simulation is often chosen as a basis for handling decision problems associated with those systems. On the one hand, the set of possible scenarios is often unknown *a priori*. On the other hand, the possible combinations of parameters is too numerous to be handled efficiently by methods such as those previously described. Consequently, decision makers must deal with the dilemma that many important types of optimization problems can be treated only by the use of simulation models, but once these problems are submitted to simulation there are no optimization methods that can adequately cope with them.

Recent developments are changing this picture. The field of metaheuristics—the domain of optimization that augments traditional mathematics with artificial intelligence and methods derived from physical, biological, or evolutionary analogs—has witnessed advances yielding effective engines for guiding a series of complex evaluations in the quest for optimal values for the decision variables, as described in Refs 4–9.

Modern simulation optimization tools are designed to solve optimization problems of the form

$$\text{Minimize } F(x) \quad (\text{objective function})$$

$$\text{Subject to : } Ax \leq b \quad (\text{constraints})$$

$$g_l \leq G(x) \leq g_u \quad (\text{requirements})$$

$$l \leq x \leq u \quad (\text{bounds}),$$

where the vector x of decision variables includes variables that range over continuous values and variables that only take on discrete values (both integer values and values with arbitrary step sizes).

The objective function $F(x)$ is typically highly complex; under the context of simulation optimization $F(x)$ represents a performance measure output by the

Figure 1. Coordination between optimizer and simulator.

simulation, and may be any mapping from a vector x of real values to a real scalar value. The constraints represented by the inequality $Ax \leq b$ are linear (given that non-linearity in the model is embedded within the simulation itself), and the coefficient matrix A and the right-hand-side values corresponding to vector b must be known. The requirements $g_l \leq G(x) \leq g_u$ impose simple upper and/or lower bounds on a function that can be linear or nonlinear, and is an output of the simulation. The values of the bounds g_l and g_u must be known constants. All the variables are bounded and some may be restricted to be discrete, as previously noted. Each evaluation of $F(x)$ and $G(x)$ requires a simulation of the system. By combining simulation and optimization, a powerful design tool results.

Optimizers designed for simulation embody the principle of separating the method from the model. In such a context, the optimization problem is defined outside the complex system. Therefore, the evaluator (i.e., the simulation model) can change and evolve to incorporate additional elements of the complex system, while the optimization routines remain the same. Hence, there is a complete separation between the model that represents the system and the procedure that is used to solve optimization problems defined within this model.

The optimization procedure uses the outputs from the system evaluator, which measures the merit of the inputs that were fed into the model. On the basis of both current and past evaluations, the method decides upon a new set of input values (Fig. 1).

Provided that a feasible solution exists, the optimization procedure ideally carries out a special search where the successively

generated inputs produce varying evaluations, not all of them improving, but which over time provide a highly efficient trajectory to the globally best solutions. The process continues until an appropriate termination criterion is satisfied (usually based on the user's preference for the amount of time devoted to the search).

The simulation optimization framework is very flexible in terms of the performance measures the decision maker wishes to evaluate. In fact, the only limitation is not on the side of the optimization engine, but on the simulation model's ability to evaluate performance based on specified values for the decision variables. In order to provide in-depth insights into the use of simulation optimization in the context of risk management, we present a practical application through the use of an illustrative example in the context of optimal portfolio selection.

Example: Selecting Optimal Portfolios of Projects. The energy industry uses project portfolio optimization to manage investments in exploration and production, as well as power plant acquisitions [10,11]. Decision makers typically wish to maximize the return on invested capital, while controlling the exposure of their portfolio of projects to various risk factors.

The following example involves a company that has 61 potential projects in its investment funnel. Each type of project requires an initial investment and a certain number of business development, engineering, and earth sciences personnel. The company has a budget limit for its investment opportunities, and a limited number of personnel of each skill category. Projects may start in different time periods, but there is a restricted window of opportunity of up to three years for

each project. The company must select a set of projects to invest in that will best further its corporate goals.

Probably the best-known model for portfolio optimization is rooted in the work of Nobel laureate Harry Markowitz. The model, called the *mean-variance model* [12], is based on the assumption that the expected portfolio returns will be normally distributed. The model seeks to balance risk and return in a single objective function, as follows.

Given a vector of portfolio returns r and a covariance matrix Q of returns, we can formulate the model as follows:

$$\text{Maximize} \quad r^T w - k w^T Q w \quad (15)$$

$$\text{Subject to :} \quad \sum_i c_i w_i = b \quad (16)$$

$$w \in \{0, 1\}, \quad (17)$$

where k represents a coefficient of the firm's risk aversion, c_i represents the initial investment in project i , w_i is a binary variable representing the decision whether to invest in project i , and b is the available budget. We will use the mean-variance model as a base case for the purpose of comparing with other selected models of portfolio performance.

To facilitate our analysis, we make use of the OptFolio® software that combines simulation and optimization into a single system specifically designed for portfolio optimization [13–15].

We examine three cases to demonstrate the flexibility of this method to enable a variety of decision alternatives that significantly improve upon traditional mean-variance portfolio optimization, and illustrate the flexibility afforded by simulation optimization approaches in terms of controlling risk. The results also show the benefits of managing and efficiently allocating scarce resources like capital, personnel, and time. The weighted average cost of capital, or

annual discount rate, used for all cases was 12%.

Case 1: Mean-Variance Approach. In this first case, we implement the mean-variance portfolio selection method of Markowitz described above. The decision is to determine participation levels (0 or 1) in each project with the objective of maximizing the expected net present value (NPV) of the portfolio while keeping the standard deviation of the NPV below a specified threshold of \$140 million. We denote the expected value of the NPV as μ_{NPV} and the standard deviation of the NPV as σ_{NPV} . This case can be formulated as follows:

$$\text{Maximize} \quad \mu_{\text{NPV}} \quad (\text{objective function}) \quad (18)$$

$$\text{Subject to:} \quad \sigma_{\text{NPV}} < \$140\text{M} \quad (\text{requirement}) \quad (19)$$

$$\sum_i c_i x_i \leq b \quad (\text{budget constraint}) \quad (20)$$

$$\sum_i p_{ij} x_i \leq P_j \quad \forall j \quad (\text{personnel constraints}) \quad (21)$$

$$\text{All projects must start in year 1} \quad (22)$$

$$x_i \in \{0, 1\} \forall i \quad (\text{binary decisions}). \quad (23)$$

The optimal portfolio has the following performance metrics:

$$\mu_{\text{NPV}} = \$394\text{M},$$

$$\sigma_{\text{NPV}} = \$107\text{M},$$

$$P(5)_{\text{NPV}} = \$176\text{M},$$

where $P(5)_{\text{NPV}}$ denotes the fifth percentile of the resulting NPV probability distribution (i.e., the probability of the NPV being lower than the $P(5)$ value is 5%).

The bound imposed on the standard deviation in Equation (19) does not seem binding. However, due to the binary nature of the decision variables, no project additions are possible without violating the bound. Figure 2 shows a graph of the probability distribution of the NPV obtained for 1000 replications of this base model. The thin line represents the expected value.

Case 2: Risk Controlled by Fifth Percentile. In the context of risk management, statistics such as variance or standard deviation of returns are not always easy to interpret and other measures may be more intuitive and useful. For example, it is clearer to say “there is a 95% chance that the portfolio return is above some value X ” than to say that the standard deviation is \$107 million. This measure can easily be implemented in a simulation optimization procedure by imposing a requirement on the fifth percentile of the resulting distribution of returns. In this case, the decision is to determine participation levels (0, 1) in each project with the objective of maximizing the expected NPV of the portfolio, while keeping the fifth percentile of the NPV distribution above the value determined in Case 1. This is achieved by imposing the requirement in Equation (25) on the model below. In other words, we want to find the portfolio that produces the maximum average return, as long as no more than 5% of the observations fall below \$176 million. Also, in this case we allow for delays in the start dates of projects, according to windows of opportunity defined for each project. In order to achieve this, we have created copies of a project that are shifted by one, two, or three periods into the future (according to the windows of opportunity defined for each project). Mutual exclusivity clauses ensure that only one start date for each project is selected. For example, to represent the fact that Project A can start at time $t = 0, 1$, or 2,

we include the following mutual exclusivity clause as a constraint:

$$\text{Project } A_0 + \text{Project } A_1 + \text{Project } A_2 \leq 1.$$

The subscript following the project name corresponds to the allowed start dates for the project, and the constraint allows at most only one of these to be chosen.

$$\text{Maximize} \quad \mu_{\text{NPV}} \quad (24)$$

Subject to :

$$P(5)_{\text{NPV}} > \$176\text{M} \quad (\text{requirement}) \quad (25)$$

$$\sum_i c_i x_i \leq b \quad (\text{budget constraint}) \quad (26)$$

$$\sum_i p_{ij} x_i \leq P_j \quad \forall j \quad (\text{personnel constraints}) \quad (27)$$

$$\sum_{m_i \in M} x_i \leq 1 \quad \forall i \quad (\text{mutual exclusivity}) \quad (28)$$

$$x_i \in \{0, 1\} \quad \forall i \quad (\text{binary decisions}), \quad (29)$$

where m_i denotes the set of mutually exclusive projects related to project i .

In this case, we have replaced the standard deviation with the fifth percentile as a

Figure 2. Mean-variance portfolio.

Figure 3. Portfolio risk controlled by $P(5)$.

Figure 4. Probability maximizing portfolio.

measure of risk containment. The resulting portfolio has the following attributes:

$$\begin{aligned}\mu_{NPV} &= \$438\text{M}, \\ \sigma_{NPV} &= \$140\text{M}, \\ P(5)_{NPV} &= \$241\text{M}.\end{aligned}$$

By using the fifth percentile instead of the standard deviation as a measure of risk, we are able to obtain an outcome that shifts the distribution of returns to the right, compared to Case 1, as shown in Fig. 3.

This case clearly outperforms Case 1. Not only do we obtain significantly better financial performance but we also achieve a higher personnel utilization rate and a more diverse portfolio.

Case 3: Probability Maximizing and Value-at-Risk. In Case 3, the decision is to determine participation levels (0, 1) in each project with the objective of maximizing the probability of meeting or exceeding the mean NPV found in Case 1. This objective is expressed in Equation (30) of the following model:

$$\text{Maximize } P(NPV \geq \$394\text{M}) \quad (30)$$

Subject to :

$$\sum_i c_i x_i \leq b \quad (\text{budget constraint}) \quad (31)$$

$$\sum_i p_{ij} x_i \leq P_j \quad \forall j \quad (\text{personnel constraints}) \quad (32)$$

$$\sum_{m_i \in M} x_i \leq 1 \quad \forall i \quad (\text{mutual exclusivity}) \quad (33)$$

$$x_i \in \{0, 1\} \forall i \quad (\text{binary decisions}). \quad (34)$$

This case focuses on maximizing the chance of achieving a goal and essentially combines performance and risk containment into one metric. The probability in Equation (30) is not known *a priori*, so we must rely on the simulation to obtain it. The resulting optimal solution yields a portfolio that has the following attributes:

$$\mu_{\text{NPV}} = \$440\text{M},$$

$$\sigma_{\text{NPV}} = \$167\text{M},$$

$$P(5) = \$198\text{M}.$$

Although this portfolio has a performance similar to the one in Case 2, it has a 70% chance of achieving or exceeding the NPV goal. As can be seen in the graph of Fig. 4, we have succeeded in shifting the probability distribution even further to the right, therefore increasing our chances of exceeding the returns obtained with the traditional Markowitz approach. In addition, in Cases 2 and 3, we need not make any assumption about the distribution of expected returns.

As a related corollary to this last case, we can conduct an interesting analysis that addresses Value-at-Risk (VaR). In traditional (securities) portfolio management, VaR is defined as the worst expected loss under normal market conditions over a specific time interval and at a given confidence level. In other words, VaR measures how much the holder of the portfolio can lose with probability $= \alpha$ over a certain time horizon [16]. In the case of project portfolios, we can define VaR as the probability that the NPV of the portfolio will fall below a specified value. Going back to our present case, the manager may want to limit the probability of incurring negative returns. In this example, we formulate the problem in a slightly different way: we still want to maximize the expected return, but we limit the probability that we incur a loss to $\alpha = 1\%$ by using the requirement shown in Equation (36) as

follows:

$$\text{Maximize} \quad \mu_{\text{NPV}} \quad (35)$$

Subject to :

$$P(\text{NPV} < 0) \leq 1\% \quad (\text{requirement}) \quad (36)$$

$$\sum_i c_i x_i \leq b \quad (\text{budget constraint}) \quad (37)$$

$$\sum_i p_{ij} x_i \leq P_j \quad \forall j \quad (\text{personnel constraints}) \quad (38)$$

$$\sum_{m_i \in M} x_i \leq 1 \quad \forall i \quad (\text{mutual exclusivity}) \quad (39)$$

$$x_i \in \{0, 1\} \forall i \quad (\text{binary decisions}). \quad (40)$$

The portfolio performance under this scenario is

$$\mu_{\text{NPV}} = \$411\text{M},$$

$$\sigma_{\text{NPV}} = \$159\text{M},$$

$$P(5) = \$195\text{M}.$$

These results from the VaR model turn out to be slightly inferior to the case where the probability was maximized. This is not a surprise, since the focus is on limiting the probability of downside risk, whereas before, the goal was to maximize the probability of obtaining a high expected return. However, this last analysis could prove valuable for a manager who wants to limit the VaR of the selected portfolio. As shown here, for this particular set of projects, a very good portfolio can be selected with that objective in mind.

CONCLUSIONS

Practically every real-world situation involves uncertainty and risk, creating a need for optimization methods that can handle uncertainty in model data and input parameters. We have briefly described two popular methods, *scenario optimization* and *robust optimization*, that seek to overcome limitations of classical optimization approaches for dealing with uncertainty, and which undertake to find high-quality solutions that are feasible under as many scenarios as possible. However, these methods are unable

to handle problems involving moderately large numbers of decision variables and constraints, or involving significant degrees of uncertainty and complexity. In these cases, simulation optimization is becoming the method of choice. The combination of simulation and optimization affords all the flexibility of the simulation engine in terms of defining a variety of performance measures as desired by the decision maker. In addition, as we demonstrate through a project portfolio selection example, modern optimization engines can enforce requirements on one or more outputs from the simulation, a feature that scenario-based methods cannot handle. Finally, simulation optimization produces results that can be conveyed and grasped in an intuitive manner, providing an especially useful tool for identifying improved business decisions under risk and uncertainty.

SIMULTANEOUS ASCENDING AUCTIONS

PETER CRAMTON
Department of Economics,
University of Maryland,
College Park, Maryland

INTRODUCTION

One of the most successful methods for auctioning many related items is the simultaneous ascending auction. This auction form was first developed for the US Federal Communications Commission's (FCC) spectrum auctions, beginning in July 1994, and has subsequently been adopted with slight variation for spectrum auctions worldwide, resulting in revenues in excess of \$250 billion. The method, first proposed by Paul Milgrom, Robert Wilson, and Preston McAfee, has been refined with experience, and extended to the sale of divisible goods in electricity, gas, and environmental markets. This article describes the method and its extensions, provides evidence of its success, and suggests what we can learn from the years of experience conducting simultaneous ascending auctions.

A key feature of the simultaneous ascending auction, at least in its basic form, is the requirement that bids be for individual items, rather than packages of items. As a result, the simultaneous ascending auction exposes bidders to the possibility that they will win some, but not all, of what they desire. In contrast, combinatorial auction methods [1] eliminate this exposure problem by allowing bidders to bid on packages of items. Nonetheless, the simultaneous ascending auction has not been supplanted by more powerful combinatorial methods, but is an essential method that any auction designer should have in his toolkit. The simultaneous ascending auction (and its variants) will remain the best method for auctioning many related items in a wide range of

circumstances, even settings where some of the goods are complements for some bidders, so the exposure problem is a real concern.

True combinatorial auctions—those that allow package bids—are also important, and indeed essential in the most complex auction environments. Still there are many situations where the simultaneous ascending auction will do a sufficiently good job in limiting the exposure problem that its other advantages (especially simplicity and price discovery) make it a preferred auction method. In other settings, where complementarities are both strong and varied across bidders, package bids are needed to improve the efficiency of the auction mechanism.

The simultaneous ascending auction is a natural generalization of the English auction when selling many goods. The key features are that all the goods are on the block at the same time, each with a price associated with it, and the bidders can bid on any of the items. The bidding continues until no bidder is willing to raise the bid on any of the items. Then the auction ends with each bidder winning the items on which it has the highest bid, and paying its bid for any items won.

The reason for the success of this simple procedure is the excellent price discovery it affords. As the auction progresses, bidders see the tentative price information and condition subsequent bids on this new information. Over the course of the auction, bidders are able to develop a sense of what the final prices are likely to be, and can adjust their purchases in response to this price information. To the extent that the price information is sufficiently good and bidders retain sufficient flexibility to shift toward their best package, the exposure problem is mitigated—bidders are able to piece together a desirable package of items, despite the constraint of bidding on individual items rather than packages.

Perhaps even more importantly, the price information helps the bidders focus their valuation efforts on the relevant range of the price space. This benefit of price discovery is ignored in the standard auction models,

which assume that each bidder costlessly knows his valuation for every possible package (or at least knows how his valuation depends on the information of others in the case of nonprivate value models). However, in practice, determining values is a costly process. When there are many items, determining precise values for all possible packages is not feasible. Price discovery focuses the bidders' valuation efforts to the relevant parts of the price space, improving efficiency and reducing transaction costs.

To further mitigate the exposure problem, most simultaneous ascending auctions allow bidders to withdraw bids. This enables bidders to back out of failed aggregations, shifting bids to more fruitful packages. However, bid withdrawals often facilitate undesirable gaming behavior, and thus the ability to withdraw bids needs to be constrained carefully. Price discovery—not bid withdrawal—is the more effective way to limit the exposure problem in simultaneous ascending auctions.

Since July 1994, the FCC has conducted dozens of spectrum auctions with the simultaneous ascending format, raising tens of billions for the US Treasury. The auctions assigned thousands of licenses to hundreds of firms. These firms provide a diversity of wireless communication services, now enjoyed by a vast majority of the population. The FCC is not alone. Countries throughout the world are now using auctions to assign spectrum. Indeed, the early auctions in Europe for third-generation (3G), mobile wireless licenses raised nearly \$100 billion. Auctions have become the preferred method of assigning spectrum and most have been simultaneous ascending auctions. (See Refs 2 and 3 for a history of the auctions.)

There is now substantial evidence that this auction design has been successful. Resale of licenses has been uncommon, suggesting that the auction assignment is nearly efficient. Revenues have often exceeded industry and government estimates. The simultaneous ascending auction may be partially responsible for the large revenues. By revealing information in the auction process, bidder uncertainty is reduced, and bidders can safely bid more aggressively. Also, revenues may increase to the extent

that the design enables bidders to piece together more efficient packages of items.

Despite the general success, the simultaneous ascending auctions have experienced a number of problems from which one can draw important lessons. One basic problem is the simultaneous ascending auction's vulnerability to revenue-reducing strategies in situations where competition is weak. Bidders have an incentive to reduce their demands in order to keep prices low, and to use bid signaling strategies to coordinate on a split of the items.

This article begins by motivating the design choices in a simultaneous ascending auction and discusses an important extension, the simultaneous clock auction, for the sale of many divisible goods. Then it describes typical rules including many important details. Next the performance of the simultaneous ascending auction is examined, identifying both strengths and weaknesses of the approach. Many refinements to the auction method, which have been introduced from early experience, are discussed.

AUCTION DESIGN

The critical elements of the simultaneous ascending auction are (i) open bidding, (ii) simultaneous sale, and (iii) no package bids. These features create a Walrasian pricing process that yields a competitive equilibrium provided (i) items are substitutes, (ii) bidders are price takers, and (iii) bid increments are negligible [3]. Of course, these conditions do not hold in practice. Some degree of market power is common, at least some items are complements, and bid increments in the 5–10% range are required to get the auction to conclude in a manageable number of rounds.

Still, the simultaneous ascending auction does perform well in practice largely because of the benefits of price discovery that come from open bidding and simultaneous sale. These benefits take two forms. First, in situations where bidder values are interdependent, price discovery may reduce the winner's curse and raise revenue [4]. Bidders are able to bid more aggressively, since they have better information about the item's value. More

importantly, when many items are for sale, the price discovery lets the bidders adapt their bidding and analysis to the price information, which focuses valuation efforts and facilitates the aggregation of a complementary package of items.

The alternative of sequential sale limits information available to bidders and limits how the bidders can respond to information. With sequential auctions, bidders must guess what prices will be in future auctions when determining bids in the current auction. Incorrect guesses may result in an inefficient assignment when item values are interdependent. A sequential auction also eliminates many strategies. A bidder cannot switch back to an earlier item if prices go too high in a later auction. Bidders are likely to regret having purchased early at high prices, or not having purchased early at low prices. The guesswork about future auction outcomes makes strategies in sequential auctions complex, and the outcomes less efficient.

Almost all the simultaneous ascending auctions conducted to date do not allow package bids. Bids are only for individual items. The main advantages of this approach are simplicity and anonymous linear prices. The auction is easily implemented and understood. The disadvantage is the exposure problem. With individual bids, bidding for a synergistic combination is risky. The bidder may fail to acquire key pieces of the desired combination, but pay prices based on the synergistic gain. Alternatively, the bidder may be forced to bid beyond its valuation in order to secure the synergies and reduce its loss from being stuck with the dogs. Bidding on individual items exposes bidders seeking synergistic combinations to aggregation risk. See Ref. 5 for an equilibrium analysis of the exposure problem in the simultaneous ascending auction (SAA), and Ref. 6 for experimental results.

Not allowing package bids can create inefficiencies. For example, suppose there are two bidders for two adjacent parking spaces. One bidder with a car and a trailer requires both spaces. He values the two spots together at \$100 and a single spot is worth nothing; the spots are perfect complements. The second bidder has a car, but no trailer. Either spot

is worth \$75, as is the combination; the spots are perfect substitutes. Note that the efficient outcome is for the first bidder to get both spots for a social gain of \$100, rather than \$75 if the second bidder gets a spot. Yet any attempt by the first bidder to win the spaces is foolhardy. The first bidder would have to pay at least \$150 for the spaces, since the second bidder will bid up to \$75 for either one. Alternatively, if the first bidder drops out early, he will “win” one spot, losing an amount equal to his highest bid. The only equilibrium is for the second bidder to win a single spot by placing the minimum bid. The outcome is inefficient and fails to generate revenue. In contrast if package bids are allowed, then the outcome is efficient. The first bidder wins both with a bid of \$75 for the package.

Unfortunately, allowing package bids creates other problems. Package bids may favor bidders seeking large aggregations due to a variant of the threshold problem. Continuing with the last example, suppose that there is a third bidder, who values either spot at \$40. Then the efficient outcome is for the individual bidders to win both spots for a social gain of $75 + 40 = \$115$. But this outcome may not occur when values are privately known. Suppose that the second and third bidders have placed individual bids of \$35 on the two spots, but these bids are topped by a package bid of \$90 from the first bidder. Each bidder hopes that the other will bid higher to top the package bid. The second bidder has an incentive to understate his willingness to push the bidding higher. He may refrain from bidding, counting on the third bidder to break the threshold of \$90. Since the third bidder cannot come through, the auction ends with the first bidder winning both spaces for \$90.

Package bidding also adds complexity. Unless the complementarities are large and heterogeneous across bidders, a simultaneous ascending auction without package bids may be preferred.

Clock Auctions

An important variation of the simultaneous ascending auction is the simultaneous clock auction. The critical difference is that bidders simply respond with quantities desired at prices specified by the auctioneer. Clock

auctions are especially effective in auctioning many divisible goods. There is a clock for each divisible good indicating its tentative price per unit quantity. Bidders express the quantity desired at the current prices. For those goods with excess demand the price is raised and bidders again express their desired quantities at the new prices. This process continues until supply just equals demand. The tentative prices and assignments then become final.

If we assume no market power and bidding is continuous, then the clock auction is efficient with prices equal to the competitive equilibrium [7].

Discrete, rather than continuous rounds, means that issues of bid increments, ties, and rationing are important. This complication is best handled by allowing bidders in each round to express their demand curves for all points along the line segment between the start of round prices and the end of round prices. Allowing a rich expression of preferences within a round makes bid increments, ties, and rationing less important. Since preferences for intermediate prices can be expressed, the efficiency loss associated with the discrete increment is less, so the auctioneer can choose a larger bid increment, resulting in a faster and less costly auction process.

TYPICAL RULES

The simultaneous ascending auction works as follows. A group of items with strong value interdependencies are up for auction at one time. A bidder can bid on any collection of items in any round, subject to an activity rule that determines the bidder's current eligibility. The auction ends when a round passes with no new bids on any item. This auction form was believed to give the bidders flexibility in expressing values and building packages of items. Common rules are described below:

Quantity Cap. To promote competition in the aftermarket, a bidder is often limited in the quantity that it can win.

Payment Rules. Typically payments are received at least at two times: a refundable deposit before the bidding begins

and a final payment for items won. The refundable deposit often defines the bidder's initial eligibility, that is, the maximum quantity of items that the bidder can bid for. A bidder interested in winning a large quantity of items would have to submit a large deposit. The deposit provides some assurance that the bids are serious. Some auctions require bidders to increase their deposit as bids increase.

Minimum Bid Increments. To assure that the auction concludes in a reasonable amount of time, minimum bid increments are specified. Bid increments are adjusted in response to bidder behavior. Typically, the bid increments are between 5 and 20%.

Activity Rule. The activity rule is a device for improving price discovery by requiring a bidder to bid in a consistent way throughout the auction. It forces a bidder to maintain a minimum level of activity to preserve its current eligibility. A bidder desiring a large quantity at the end of the auction (when prices are high) must bid for a large quantity early in the auction (when prices are low). As the auction progresses, the activity requirement increases, reducing a bidder's flexibility. The lower activity requirement early in the auction gives the bidder greater flexibility in shifting among packages early on when there is the most uncertainty about what will be obtainable.

Number of Rounds per Day. A final means of controlling the pace of the auction is the number of rounds per day. Typically, fewer rounds per day are conducted early in the auction when the most learning occurs. In the later rounds, there is much less bidding activity, and the rounds can occur more quickly.

Stopping Rule. A simultaneous stopping rule is used to give the bidders maximum flexibility in pursuing backup strategies. The auction ends if a single round passes in which no new bids

are submitted on any item. In auctions with multiple stages (later stages have higher activity requirements), the auction ends when no new bids are submitted in the final stage. Few or no bids in an earlier stage shifts the auction to the next stage.

Bid Information. The most common implementation is full transparency. Each bidder is fully informed about the identities of the bidders and the size of the deposits. High bids and bidder identities are posted after each round. In addition, all bids and bidder identities are displayed at the end of each round, together with each bidder's eligibility.

Bid Withdrawal. To limit the exposure problem, high bidders can withdraw their bids subject to a bid withdrawal penalty. If a bidder withdraws its high bid, the auctioneer is listed as the highest bidder and the minimum bid is the second-highest bid for that item. The second-highest bidder is in no way responsible for the bid, since this bidder may have moved on to other items. If there are no further bids on the item, the auctioneer can reduce the minimum bid. To discourage insincere bidding, there are penalties for withdrawing a high bid. The penalty is the larger of 0 and the difference between the withdrawn bid and the final sale price. This penalty is consistent with the standard remedy for breach of contract. The penalty equals the damage suffered by the seller as a result of the withdrawal.

PERFORMANCE OF THE SIMULTANEOUS ASCENDING AUCTION

Since we do not observe the values that the firms place on items, it is impossible to directly assess the efficiency of the simultaneous ascending auction from field data. Nonetheless, we can indirectly evaluate the auction design from the observed behavior in spectrum auctions [2,8].

Revenue is a first sign of success. Auction revenues have been substantial.

A second indicator of success is that the auctions tend to generate market prices. Similar items tend to sell for similar prices. Limited substitution, however, can cause some price anomalies [9].

A third indicator of success is the formation of efficient license aggregations. Bidders did appear to piece together sensible license aggregations in the early auctions.

An analysis of the US auction data in early auctions shows evidence of local synergies [10]. Consistent with local synergies, this study finds that bidders did pay more when competing with a bidder holding neighboring licenses. Hence, bidders did bid for synergistic gains and, judging by the final footprints, often obtained them.

DEMAND REDUCTION AND COLLUSIVE BIDDING

Despite the apparent success of these auctions, an important issue limiting both efficiency and revenues is demand reduction and collusive bidding. These issues become important in multiple-item auctions.

For example, suppose there are two identical items and two bidders (Large and Small). Large has a value of \$100 per item (\$200 for both); whereas Small has a value of \$90 for one item and values the second at \$0. In a simultaneous ascending auction with a reserve price less than \$80, the unique equilibrium outcome is for each to bid for a single item, so that the auction ends at the reserve price. Large prefers ending the auction at the reserve price, winning a single item for a profit of more than \$20, since to win both items Large would have to raise the price on both items above \$90 (it is a dominant strategy for Small to bid up to \$90 on each), which results in a profit of less than \$20. The demand reduction by Large harms both efficiency and seller revenues.

This logic is quite general. In multiunit uniform-price auctions, typically every equilibrium is inefficient [11]. Bidders have an incentive to shade their bids for multiple units, and the incentive to shade increases with the quantity being demanded. Hence, large bidders will shade more than small

bidders. This differential shading creates an inefficiency.

The simultaneous ascending auction can be viewed as an ascending-bid version of a uniform-price auction. For items that are close substitutes, the simultaneous ascending auction has generated near uniform prices. However, the incentives for demand reduction and collusive bidding are more likely pronounced in an ascending version of the uniform-price auction [12]. To illustrate this, consider a simple example with two identical goods and two risk-neutral bidders. Suppose that for each bidder the marginal value of winning one item is the same as the marginal value of winning a second item. These values are assumed independent and private, with each bidder drawing its marginal value from a uniform distribution between 0 and 100. First consider the sealed-bid uniform-price auction where each bidder privately submits two bids and the highest two bids secure units at a per-unit charge equal to the third-highest bid. There are two equilibria to this sealed-bid auction: a demand-reducing equilibrium where each bidder submits one bid for \$0 and one bid equal to its marginal value; and a sincere equilibrium where each bidder submits two bids equal to its marginal value. The sincere equilibrium is fully efficient in that both units will be awarded to the bidder, who values them more. The demand-reducing equilibrium, however, raises zero revenue (the third-highest bid is zero) and is inefficient since the bidder with the higher value wins only one unit.

Next consider the same setting, but where an ascending version of the auction is used. Specifically, view the ascending auction as a two-button auction where there is a price clock that starting from price 0 increases continuously to 100. The bidders depress the buttons to indicate the quantity they are bidding for at every instant. The buttons are “nonre-pushable” meaning a bidder can decrease its demand but cannot increase it. Each bidder observes the price and can observe how many buttons are being depressed by its opponent. The auction ends at the first price such that the total number of buttons depressed is less

than or equal to two. This price is the clearing price. Each bidder will win the number of units he demands when the auction ends, and is charged the clearing price for each unit he wins. In this game, if dominated strategies are eliminated, there is a unique equilibrium in which the bidding ends at a price of 0, with both bidders demanding just a single unit. The reason is that each bidder knows that if it unilaterally decreases its bidding to one unit, the other bidder will instantaneously end the auction, as argued above. But since the bidder prefers the payoff from winning one unit at the low price over its expected payoff of winning two units at the price high enough to eliminate the other bidder from the auction, the bidder will immediately bid for just one unit, inducing an *immediate* end to the auction. Thus, the only equilibrium here is analogous to the demand-reducing equilibrium in the sealed-bid uniform-price auction. The efficient equilibrium does not exist. This example shows that the incentives to reduce demand can be more pronounced in an open auction, where bidders have the opportunity to respond to the elapsed bidding. The 1999 German GSM spectrum auction, which lasted just two rounds, illustrates this behavior [13]; see Ref. 14 for experimental evidence.

For an auction format like the FCC’s, where the bidding occurs in rounds and bidding can be done on distinct units, there exist equilibria where the bidders coordinate a division of the available units at low prices relative to their own values [15,16]. Bidders achieve these low-revenue equilibria by threatening to punish those bidders, who deviate from the cooperative division of the units. The idea in these articles is that bidders have the incentives to split up the available units thereby ending the auction at low prices.

Collusive bidding strategies in the FCC’s DEF auction are examined in Ref. 12. During the DEF auction, the FCC and the Department of Justice observed that some bidders used bid signaling to coordinate the assignment of licenses. Specifically, some bidders engaged in *code bidding*. A code bid uses the trailing digits of the bid to tell other bidders on which licenses to bid or not to bid. Since bids were often in millions of dollars, yet were

specified in dollars, bidders at negligible cost could use the last three digits—the trailing digits—to specify a market number. Often, a bidder (the sender) would use these code bids as retaliation against another bidder (the receiver), who was bidding on a license desired by the sender. The sender would raise the price on some market that the receiver wanted, and use the trailing digits to tell the receiver on which license to cease bidding. Although the trailing digits are useful in making clear which market the receiver is to avoid, *retaliating bids* without the trailing digits can also send a clear message. The concern of the FCC is that this type of coordination may be collusive and may dampen revenues and efficiency.

Following the experience in the DEF auction, the FCC restricted bids to a whole number of bid increments above the standing high bid. This eliminates code bidding, but it does nothing to prevent retaliating bids. Retaliating bids may be just as effective as code bids in signaling a split of the licenses when competition is weak.

The auctioneer has many instruments to reduce the effectiveness of bid signaling. These include the following:

- *Concealing Bidder Identities.* This prevents the use of targeted punishments against rivals. Unless there are strong efficiency reasons for revealing identities, anonymous auctions may be preferable.
- *Setting High Reserve Prices.* High reserve prices reduce the incentive for demand reduction in a multiple-item auction, because as the reserve price increases the benefit from reducing demands falls. Moreover, higher reserve prices reduce the number of rounds that the bidders have to coordinate a split of the licenses and still face low prices.
- *Offering Preferences for Small Businesses and Nonincumbents.* Competition is encouraged by favoring bidders that may otherwise be disadvantaged *ex ante*. In the DEF auction, competition for the D and E licenses could have been increased by extending small business

preferences to the D and E blocks, rather than restricting the preferences to the F block.

- *Offering Larger Licenses.* Many small licenses are more easily split up. At the other extreme, a single nationwide license is impossible to split up. Such extreme bundling may have negative efficiency consequences, but improves revenues.

The inefficiencies of demand reduction can be eliminated with a Vickrey auction or more practically with a clock-proxy auction [9,17].

CONCLUSION

A simultaneous ascending auction is a sensible way to auction many items. This approach has been used with great success to auction spectrum, energy, and pollution permits. The process yields a competitive equilibrium in simple settings. Evidence from practice suggests that the desirable properties of the design are largely robust to practical complications, such as mild complementarities. However, when competition is weak, there is a tendency for collusive bidding strategies to appear, especially in the fully transparent implementation in which all bids and bidder identities are revealed after each round.

When some items are complements, the simultaneous ascending auction suffers from the exposure problem, since package bids are not allowed. To limit this problem, the auction rules typically allow the withdrawal of standing high bids. This allows a bidder to back out of a failed aggregation. Interestingly, an examination of withdrawals in the FCC spectrum auctions reveals that the withdrawals typically were not used for this desired purpose, but rather were mostly for undesirable bid signaling. As a result, current auctions limit a bidder's withdrawals to occur in just a few rounds of the auction.

Recent experience with simultaneous ascending auctions suggests that there are many advantages to the clock variation [7]. Most importantly, the ability of bidders to engage in tacit collusion through bid signaling is greatly reduced. Demand reduction,

however, remains a problem in the standard clock auction. However, demand reduction can be eliminated with the package clock auction [9].

INTRODUCTION

Optimization methods play an important role in many disciplines such as signal processing, communication networks, neural networks, economics, operations research, manufacturing systems, and so on. As examples, consider a communication network where the goal is to optimally allocate link bandwidth amongst competing flows, or a manufacturing plant where the goal is to decide the optimal order in which to allocate machine capacity for manufacturing various products. These are two specific instances of innumerable problems across various disciplines that fall within the broad category of optimization problems. Such problems are typically characterized via an objective function whose optimum constitutes the desired solution. These problems can be deterministic or stochastic, or they can be static or dynamic.

A general optimization problem (that we shall be concerned about in this article) has the following form:

$$\text{Find } \theta^* \text{ for which } J(\theta^*) = \min_{\theta \in C} J(\theta), \quad (1)$$

where $J: \mathcal{R}^N \rightarrow \mathcal{R}$ is called the *objective function*, θ is a tunable N -dimensional parameter and $C \subset \mathcal{R}^N$ is the constraint set in which θ takes values. If one has complete information about the function J , its derivatives, and so on, and about the set C , then Equation (1) is a deterministic optimization problem. If on the other hand, J is obtained as $J(\theta) = E_{\xi}[h(\theta, \xi)]$, where

$E_{\xi}[\cdot]$ is an expected value of observations or samples $h(\theta, \xi)$ with *random noise* ξ , and one is allowed to observe only these samples (without really knowing J), then one is in the realm of stochastic optimization. As we shall see subsequently, many times one resorts to search algorithms in order to find a minimum, that is, a solution to Equation (1). In stochastic optimization algorithms, it is not uncommon to make a random choice in the search direction. Thus, a second distinction between deterministic and stochastic optimization problems lies in the way in which search progresses: a random search algorithm results in the optimization setting being stochastic.

Suppose now that J has the form $J(\theta) = \sum_{i=1}^N E[h_i(X_i)]$, where X_i is the “state” of an underlying process in stage i (we have N stages in all here) and h_i denotes a stage- and state-dependent cost function. Let $\theta = (\theta_1, \dots, \theta_N)^T$, with each θ_j being a scalar ($j = 1, \dots, N$) and let X_i depend on $\theta_1, \dots, \theta_i$, $i = 1, \dots, N$. The idea is that optimization can be done one stage at a time over N stages after observing the state X_i in each stage i . The value θ_i in stage i (of the parameter) has a bearing on the cost of all subsequent stages $i+1, \dots, N$. This is a problem of dynamic optimization. Approaches such as dynamic programming are often used to solve dynamic optimization problems. Other manifestations of dynamic optimization, say over an infinite number of stages or in continuous time, also exist. In static optimization on the other hand, a one-shot optimization is performed even when there are multiple stages; that is, the parameters $\theta_1, \dots, \theta_N$ are optimized all at once in the first stage itself. There may also be only a single stage instead of multiple stages. Broadly speaking while in dynamic optimization one makes decisions “on the fly” as states are revealed, in static optimization, there is no explicit notion of time or perhaps even state as all decisions can be made at once. In this article, we shall be concerned with certain gradient estimation techniques for

stochastic optimization problems. We shall primarily consider the static optimization setting involving just a single stage. It may be worth noting that in many optimization problems, one is concerned with maximizing an objective unlike Equation (1) that considers minimization. However, such problems can be recast as Equation (1) by considering the objective function to be $-J(\theta)$ instead of $J(\theta)$.

We now provide an overview of the remainder of this article. In the next section, we briefly discuss well-known local search algorithms, mainly from the viewpoint of deterministic optimization. The algorithms that we review subsequently such as the finite-difference stochastic approximation (FDSA), simultaneous perturbation stochastic approximation (SPSA), higher-order algorithms, smoothed functional algorithms, and so on, are all local search algorithms, though for the stochastic optimization setting. These algorithms can be viewed as stochastic analogs of the deterministic algorithms in the next section.

A fundamental stochastic algorithm is the Robbins–Monro (R–M) algorithm [1] that estimates the zeros of a function. Most stochastic search algorithms can be viewed as variants of the R–M algorithm. In particular, the convergence analysis of stochastic search algorithms follows along the lines of that of the R–M algorithm. Hence in the third section, we give an overview of the R–M algorithm and discuss issues related to its convergence.

Amongst the first stochastic gradient search algorithms based on estimating the gradient of the objective function, is the FDSA algorithm [2] due to Kiefer and Wolfowitz. We review this algorithm in the section titled “Finite-Difference Stochastic Approximation.” As we shall see, FDSA is not efficient under high-dimensional parameters since the number of function measurements required to estimate the gradient using FDSA grows linearly with the parameter dimension.

Spall invented the SPSA algorithm [3,4] that is remarkable in that it requires only two function measurements at each instant, regardless of the parameter dimension by

randomly perturbing all parameter components. This algorithm has been found to be very efficient in various settings. Its development has resulted in a flurry of research activity during the last two decades with a significant amount of research focused around this algorithm. This research includes not just theoretical analyses and applications of SPSA in various disciplines, but also the development of similar algorithms. We review the SPSA algorithm in the section titled “Simultaneous Perturbation Stochastic Approximation.”

In the section titled “Variations to the Basic Scheme,” we review the development of algorithms that have a flavor similar to SPSA and possess a finite-difference structure in most cases. We discuss in particular, deterministic perturbations SPSA, higher-order algorithms that is those that estimate not just the gradient but also the Hessian, and the smoothed functional algorithm. We also review developments in multitimescale algorithms that are seen to be useful in areas such as simulation optimization and adaptive control. Further, we discuss developments involving applications of SPSA and similar algorithms on an optimization problem that is similar to Equation (1) but with functional (inequality) constraints.

Finally, in the last section, we provide an overview of the many diverse applications where SPSA and some of the SPSA-type algorithms have been successfully applied. Our aim in doing so is to bring to the fore the fact that SPSA and the related algorithms constitute powerful methods for stochastic optimization that have been found useful in many disciplines of science and engineering. Excellent (though less recent) surveys on the SPSA algorithm are available in Refs 5 and 6. The current survey is a more up-to-date account of the developments related to SPSA and as mentioned, also covers the algorithms developed along the lines of SPSA.

ALGORITHMS FOR LOCAL SEARCH

Search algorithms can be broadly classified into two categories: global search and local search algorithms. Global (resp. local) search

algorithms look for the global (resp. local) minimum. For the optimization problem (Eq. 1), we say that $\theta^* \in C$ is a global minimum of the function J if $J(\theta^*) \leq J(\theta) \forall \theta \in C$. On the other hand, we say that $\theta^* \in C$ is a local minimum of J if there exists an $\epsilon > 0$ such that $J(\theta^*) \leq J(\theta) \forall \theta \in C$ with $\|\theta - \theta^*\| < \epsilon$. Many times, the norm $\|\cdot\|$ is chosen to be the Euclidean norm. A well-known example of a global search technique is simulated annealing [7,8]. Even while it is desirable to obtain a global minimum, global search techniques are known to be very slow. Hence, quite often, the only acceptable option is to use local search methods.

A typical local search algorithm (ignoring noise effects for now) has the form [9–11]

$$\theta_{n+1} = \theta_n - a_n D(\theta_n)^{-1} \nabla J(\theta_n), \quad (2)$$

where a_n , $n \geq 0$ is called the *step-size* sequence; that is, a sequence of positive real numbers that asymptotically diminish to zero, $D(\theta_n)$ is a positive definite $N \times N$ matrix, and $\nabla J(\theta_n)$ denotes the gradient of $J(\theta)$ evaluated at $\theta = \theta_n$. Here $J(\cdot)$ is the objective function to be minimized (Eq. 1). Note that if $\nabla J(\theta_n)$ and $D(\theta_n)$ are analytically known quantities, then recursion Equation (2) can proceed as is and we are in the domain of deterministic optimization. On the other hand, if $J(\theta_n)$ is of the form $J(\theta_n) = E_\xi[h(\theta_n, \xi)]$ and we only have access to noisy cost samples $h(\theta_n, \xi)$, then quantities $\nabla J(\theta_n)$ and, in many cases, $D(\theta_n)$ have to be estimated. The algorithms for stochastic optimization inherently have randomness because of the presence of noise in the cost samples. In addition, the estimators of $\nabla J(\theta_n)$ and $D(\theta_n)$ may introduce additional randomness (as happens for instance in the SPSA algorithm, see the section titled “Simultaneous Perturbation Stochastic Approximation,” as well as the higher-order and SF algorithms in the section titled “Variations to the Basic Scheme”), resulting in the search direction being random as well. In order to bring out ideas clearly, we assume in the remainder of this section that $\nabla J(\theta_n)$ and $D(\theta_n)^{-1}$ are analytically known quantities for the updates as in Equation (2); that is, we have a deterministic optimization

framework. In the later sections, however, we shall be primarily concerned with the stochastic optimization setting. The algorithms there shall correspond to the stochastic analogs of Equation (2).

Given $\theta \in \mathcal{R}^N$ such that $\nabla J(\theta) \neq 0$, any $x \in \mathcal{R}^N$ satisfying $x^T \nabla J(\theta) < 0$ is called a *descent* direction since the directional derivative $x^T \nabla J(\theta)$ along the direction x is negative and thus by a Taylor’s expansion, one obtains

$$J(\theta + a_n x) = J(\theta) + a_n x^T \nabla J(\theta) + o(a_n). \quad (3)$$

Here, given two real-valued sequences $\{x_n\}$ and $\{y_n\}$, we say that $x_n = o(y_n)$ if $x_n/y_n \rightarrow 0$ as $n \rightarrow \infty$. From the above, one can see that $J(\theta + a_n x) < J(\theta)$ for a_n sufficiently small. Now since $D(\theta_n)$ is a positive definite matrix, so is $D(\theta_n)^{-1}$. Hence, $x = -D(\theta_n)^{-1} \nabla J(\theta_n)$ is a descent direction as well. Algorithms that update along descent directions are also called *descent algorithms*.

The following well-known algorithms are special cases of Equation (2):

1. *Gradient Algorithm*. This is the most commonly used descent algorithm. Here $D(\theta_n) = I$ (the N -dimensional identity matrix). This is also called the *steepest descent* algorithm since its updates are strictly along the direction of negative gradient.
2. *Jacobi Algorithm*. In this algorithm, $D(\theta_n)$ is set to be an $N \times N$ -diagonal matrix with its i th diagonal element $\nabla_{i,i}^2 J(\theta_n)$, that is, the second partial derivative of $J(\theta)$ with respect to the i th component of θ evaluated at $\theta = \theta_n$. The latter also corresponds to the (i,i) th element of the Hessian $\nabla^2 J(\theta_n)$. For $D(\theta_n)$ to be a positive definite matrix in this case, it is easy to see that all elements $\nabla_{i,i}^2 J(\theta_n)$, $i = 1, \dots, N$ need be positive.
3. *Newton Algorithm*. Here $D(\theta_n)$ is chosen to be $\nabla^2 J(\theta_n)$, the Hessian of $J(\theta_n)$.

The $D(\theta_n)$ matrices in the Jacobi and Newton algorithms by themselves need not be

positive definite (for all n) in general as they vary with θ_n and hence, should be projected appropriately after each parameter update so as to ensure that the resulting matrices are positive definite (pp. 88–98, [9]). With proper scaling provided by the $D(\theta_n)$ matrix, the descent directions obtained using Jacobi and Newton algorithms are preferable to the one using the gradient algorithm. However, obtaining estimates of the Hessian in addition to the gradient, in general requires much more computational effort. Our main focus in this paper is on gradient-based algorithms and subsequently we shall also review some development on higher-order (Newton/Jacobi) algorithms.

THE ROBBINS–MONRO ALGORITHM

We shall from now on be primarily concerned with the stochastic optimization problem. Given the function J , a first order necessary condition for a local minimum θ^* in the interior of C is $\nabla J(\theta^*) = 0$. The local search algorithms of the previous section aim to achieve this by converging to a point θ^* for which $\nabla J(\theta^*) = 0$ if θ^* is in the interior of C . Further, if θ^* is a local minimum that is on the boundary of C , the search algorithm can converge to θ^* regardless of whether or not $\nabla J(\theta^*) = 0$. The condition $\nabla J(\theta^*) = 0$ is not a sufficient condition for a local minimum. Thus, in principle, θ^* could be a maximum or a saddle point (minimum along some components of the function and maximum along some others) if there is one as well. It is normally the case, however, that stochastic search algorithms under sufficiently general noise conditions do indeed tend to converge to a local minimum.

The development in the area of root-finding stochastic algorithms (not necessarily for optimization) started in a seminal paper by Robbins and Monro [1]. The problem of finding the roots of a function $L : \mathcal{R}^N \rightarrow \mathcal{R}^N$ under noisy observations was considered in Ref. 1. The algorithms of the previous section in the stochastic optimization case can be considered to be special cases of this algorithm. For instance, in the case of the gradient algorithm, one can consider

$L(\theta) = \nabla J(\theta)$. All the algorithms that we review in the subsequent sections are based on the R–M algorithm. Because of its importance, we review the R–M algorithm in detail here.

The R–M Algorithm

Let $g(\theta, \xi_n)$ denote the n th observed sample of $L(\theta)$ when the parameter is $\theta \in \mathcal{R}^N$ and the sample is corrupted by noise $\xi_n \in \mathcal{R}^K$. Here $g : \mathcal{R}^N \times \mathcal{R}^K \rightarrow \mathcal{R}^N$ is such that $E_{\xi}[g(\theta, \xi_n)] = L(\theta)$. The noise random vectors $\xi_n, n \geq 1$ could be independent and identically distributed (i.i.d.) or more generally, may depend on the underlying system state. As we explain below, this setting is more general than the original setting considered in Ref. 1.

Let $\{a_n, n \geq 1\}$ be a deterministic sequence of positive real numbers that satisfy the property

$$\sum_n a_n = \infty, \sum_n a_n^2 < \infty. \quad (4)$$

The first condition above is required to ensure that the algorithm does not prematurely converge. The second condition is required to reduce the effect of noise. We discuss issues related to the convergence of the algorithm in the next section. Common examples of $\{a_n, n \geq 1\}$ include (a) $a_n = c_1/(n + c_2)$, (b) $a_n = c_1/(n + c_2)^\alpha$, $\alpha \in (0.5, 1)$, (c) $a_n = (\ln(n + c_1))/(n + c_2)$, (d) $a_n = c_1/(c_2 + n \ln n)$, and so on, for some suitably chosen constants c_1 and $c_2 > 0$.

Note that $g(\theta, \xi_n)$ can be written as $g(\theta, \xi_n) = L(\theta) + M_{n+1}$, where $M_{n+1} = g(\theta, \xi_n) - L(\theta)$, $n \geq 0$. The R–M stochastic approximation algorithm is as follows: for $n \geq 0$,

$$\theta_{n+1} = \theta_n - a_n(L(\theta_n) + M_{n+1}), \quad (5)$$

where θ_n is the n th update of the parameter θ . If θ is constrained to take values within a prescribed set $C \subset \mathcal{R}^N$ as with Equation (1), one can project after each iterate the value of θ_{n+1} to the set C . The new value of θ_{n+1} then corresponds to its projected value after the update.

The original R–M algorithm in Ref. 1 considered the form of Equation (5) of the

updates by assuming that the random vectors M_{n+1} have the zero-vector as their mean. Further, these vectors are independent and have a common distribution. In Ref. 1, it is not assumed that the samples have the form $g(\theta_n, \xi_n)$. The latter is a more general, nonadditive noise form. When the samples are obtained in the form $g(\theta_n, \xi_n)$, the random vectors M_{n+1} form a “martingale difference” sequence and are no longer i.i.d.. We say M_{n+1} , $n \geq 0$ form a martingale difference sequence if the conditional expectation $E[M_{n+1} | \theta_i, M_{i+1}, 0 \leq i \leq n-1, \theta_n] = 0$ with probability one. Analyses for the more general case are available for instance in Refs 12 and 13. Next, we briefly discuss the convergence of the algorithm 5.

Convergence of the Algorithm

We consider the form (Eq. 5) of the algorithm by assuming M_{n+1} , $n \geq 0$ to be a martingale difference sequence. The form of M_{n+1} , $n \geq 0$ is considered in Ref. 1 that is, of independent random vectors having a common distribution and with the zero-vector as their mean is a special case of them being a martingale difference sequence. Convergence in the mean square (m.s.) sense was shown in Ref. 1. The general case has been covered, for instance, in Refs 12 and 13 where convergence in the almost sure (a.s.) sense is shown. A good account of probability theory, including the various notions of convergence for a sequence of random vectors, can be found in Ref. 14. In order to prove convergence of recursions such as Equation (5), one needs to first ensure that the parameter updates in these recursions remain stable or uniformly bounded; that is, do not blow up. We briefly discuss this aspect below. However, before we proceed, it is important to make the point that assuming this is true; that is, the parameter updates are uniformly bounded and suppose they converge in the a.s. sense, then it can be shown that they also converge in the m.s. sense. The converse is however not true even when updates are bounded.

If the set C in which θ takes values is a bounded well-defined subset of $\mathcal{R}^N$, one would normally project the parameter after each update (as mentioned above) to the set

C , thereby ensuring that the obtained parameters are both feasible (i.e., take values in the set where they are allowed to take values in) and remain bounded. Even if C is unbounded but one roughly knows the region of the space where the “asymptotically stable” equilibria lie, one could choose a large bounded set (a subset of C) that contains the above region and use projection to ensure that the updates remain bounded. This would also imply that the remainder of the space is not visited by the algorithm which may, in fact, be good since the algorithm in such a case would not waste its resources in exploring the region of the space that does not contain the equilibria. The projection technique is often used to ensure the stability of iterations. Other approaches to prove stability of the iterations (when the constraint region is unbounded) include the stochastic Lyapunov technique [13] and the recently proposed approach in Refs 12 and 15, whereby one does a scaling of the original iteration (Eq. 5) to approximate the same with a deterministic process in a manner similar to the construction of the fluid model of Refs 16 and 17. This approach is remarkable in that using just an ordinary differential equation (ODE)–based analysis, one can prove stability of the original random recursion. Another approach [18] is to define a constraint region for the updates, use projection as explained above, but gradually increase the size of the constraint region as iterations progress.

An ODE-based argument whereby one shows that the noise effects vanish asymptotically under the step-size conditions (Eq. 4) and that the resulting iteration follows asymptotically a limiting ODE, once stability of the updates (discussed above) is ensured, has been followed in Refs 12, 13, 19–21. We remark here that the ODE used to prove stability of the stochastic updates in Ref. 15 is different from the ODE used to show convergence once stability is established. The former ODE corresponds to the scaled stochastic recursion there while the latter is described below and is commonly used to establish convergence given that the updates are stable. The ODE associated with Equation (5) is

$$\dot{\theta}(t) = -L(\theta(t)), \quad (6)$$

where $\dot{\theta}(t)$ is the derivative of $\theta(t)$ relative to t . If θ^* is a unique asymptotically stable equilibrium of Equation (6), then one can prove under certain conditions a.s. convergence to θ^* that is, $\theta_n \rightarrow \theta^*$ a.s. as $n \rightarrow \infty$, [12,13,21]. In the case of multiple isolated equilibria, the algorithm shall converge to one amongst them, depending on the noise and initial condition. By isolated equilibria, we mean that one can construct certain sufficiently small open neighborhoods such that exactly one equilibrium is contained within each neighborhood. Results for the case when the set of stable fixed points comprises of certain “invariant sets” that are not necessarily isolated equilibria, are available in Refs 12, 13 and 22.

The R–M algorithm, when applied in the context of gradient-based schemes, aims at finding the root of the function gradient when it is not analytically known but only noisy samples are available. In what follows, we consider the stochastic optimization problem of finding roots of the function gradient under noisy samples.

FINITE-DIFFERENCE STOCHASTIC APPROXIMATION

In the R–M algorithm (Eq. 5), suppose that $L(\theta_n) = \nabla J(\theta_n)$. Then one can show that under certain conditions, Equation (5) converges to a local minimum of J . We are thus in the domain of stochastic gradient algorithms; that is, gradient algorithms with noise (see the section titled “Algorithms for Local Search”). Suppose $J(\theta) = E_\xi[h(\theta, \xi)]$, that is, we are in the stochastic optimization setting. If $\nabla h(\theta, \xi)$ exists for any given noise sample ξ , then under certain regularity conditions, for instance as given in Refs 23–25, one can interchange the expectation and gradient operators to obtain $\nabla J(\theta) = E[\nabla h(\theta, \xi)]$. In such a case, Equation (5) can be applied with $M_{n+1} = (\nabla h(\theta_n, \xi_n) - L(\theta_n))$ as the martingale difference term to obtain asymptotic convergence to a local minimum of J . Infinitesimal perturbation analysis and its variants are largely based on this idea 23–27. In practice, however, it is difficult to have access to direct gradient measurements. It

is also possible that while the function J is continuously differentiable with bounded higher-order derivatives, the function h is not (differentiable). One therefore, requires other gradient estimation techniques.

The first approach in this direction goes under the name of FDSA [2]. The basic algorithm here is still Equation (5), except with $L(\theta) = \nabla J(\theta)$ approximated by a finite-difference estimate (Eq. 7) with effective noise $M_{n+1} = (M_{n+1}^i, i = 1, \dots, N)^T$, where $M_{n+1}^i = (\xi_{n+1,i}^+ - \xi_{n+1,i}^-)/2c_n$, $n \geq 0$. We assume that the vectors $(\xi_{n+1,i}^+ - \xi_{n+1,i}^-, i = 1, \dots, N)^T$, $n \geq 0$ form a martingale difference sequence. The algorithm is thus in the form of Equation (5). The quantity multiplying $a(n)$ on the RHS of Equation (5), that is, $(\nabla J(\theta_n) + M_{n+1})$ (assuming $L(\theta_n) = \nabla J(\theta_n)$) is approximated here by the N -vector $Y_n = (Y_{n,1}, \dots, Y_{n,N})^T$, where

$$Y_{n,i} = \frac{(J(\theta_n + c_n e_i) + \xi_{n+1,i}^+) - (J(\theta_n - c_n e_i) + \xi_{n+1,i}^-)}{2c_n} \quad (7)$$

$$= \frac{J(\theta_n + c_n e_i) - J(\theta_n - c_n e_i)}{2c_n} + \frac{\xi_{n+1,i}^+ - \xi_{n+1,i}^-}{2c_n}, i = 1, \dots, N. \quad (8)$$

Here e_i denotes the unit vector with 1 in the i th place and 0 elsewhere. In Equation (7), $J(\theta_n + c_n e_i) + \xi_{n+1,i}^+$ and $J(\theta_n - c_n e_i) + \xi_{n+1,i}^-$ correspond to independent noise-corrupted measurements of the objective function $J(\cdot)$ under parameters $\theta_n + c_n e_i$ and $\theta_n - c_n e_i$, respectively. In the following, we simply represent the other gradient estimates in a similar manner, as in Equation (8) instead of Equation (7), to suit the form $(L(\theta_n) + M_{n+1})$ in Equation (5).

The scalar parameters c_n , $n \geq 0$ should be carefully chosen so that $c_n \rightarrow 0$ (as $n \rightarrow \infty$) at a slow rate in order that the variance in the FDSA estimates does not blow up. We explain conditions on c_n , $n \geq 0$ in the case of the SPSA algorithm in the next section. Similar conditions hold for the FDSA algorithm as well. Quite often, it makes sense to simply set $c_n = \delta$ for a ‘small’ $\delta > 0$ as has been done in Refs 28–30 (see also p. 15 of Ref. 13 for a discussion along these lines). In Refs 31 and

32, it is seen that the use of common random numbers, that is $\xi_{n,i}^+ = \xi_{n,i}^-$ reduces the estimator variance. This may be possible in some simulation-based settings with random variables obtained from the same pseudorandom sequence. However, in most practical applications, this is difficult to achieve even with simulation. FDSA [2] is also often called the *Kiefer–Wolfowitz algorithm* in honor of its inventors.

A variant of FDSA that is based on one-sided differences is described next. The gradient estimates in Equation (8) are also called *two-sided finite-difference estimates* while those that we describe below in Equation (9) are called *one-sided estimates*. In one-sided FDSA, one uses Equation (5) with the following estimate of $(\nabla J(\theta_n) + M_{n+1})$ in place of Equation (8) (assuming $L(\theta_n) = \nabla J(\theta_n)$):

$$Y_{n,i} = \frac{J(\theta_n + c_n e_i) - J(\theta_n)}{c_n} + \frac{\xi_{n+1,i}^+ - \xi_{n+1,i}^-}{c_n}, \quad 1, \dots, N. \quad (9)$$

Note that the estimates (Eq. 8) require $2N$ function measurements in order to obtain one estimate Y_n of the gradient. With Equation (9), one requires $(N+1)$ function measurements to obtain a gradient estimate. In the setting of simulation optimization [11,23,26,27,30,33,34], where one does not have access to function measurements but simulates the whole system, one requires in effect $2N$ (resp. $(N+1)$) parallel simulations of the entire system when using two-sided (resp. one-sided) estimates. This makes the procedure highly computationally expensive when N becomes large and therefore, one requires more efficient methods for gradient estimation.

SIMULTANEOUS PERTURBATION STOCHASTIC APPROXIMATION

Spall [3,4] invented a remarkable algorithm that has become popular by the name simultaneous perturbation stochastic approximation (SPSA). It is remarkable in that it requires only two function measurements for a parameter of any dimension

(i.e., any $N \geq 1$) and exhibits fast convergence (normally faster than FDSA). The two function measurements are obtained from simultaneously perturbing all components of the parameter vector randomly. The two perturbed parameters correspond to $\theta_n + c_n \Delta_n$ and $\theta_n - c_n \Delta_n$, respectively, where $\Delta_n = (\Delta_{n,1}, \dots, \Delta_{n,N})^T$ is a vector of independent, mean-zero, symmetric random variables that satisfy an inverse moment bound. Most often, one assumes these random variables to be distributed according to the symmetric Bernoulli distribution with $\Delta_{n,i} = \pm 1$ w.p. $1/2$, $i = 1, \dots, N$, $n \geq 0$. In fact, it is found in Ref. 35 that under certain conditions, the optimal distribution on components of the simultaneous perturbation vector is a symmetric Bernoulli distribution. The authors in Ref. 35 obtain this result under two separate objectives: (i) minimize the mean square error of the estimate and (ii) maximize the likelihood that the estimate remains in a symmetric bounded region around the true parameter.

As with the previous section, we assume here as well that $L(\theta)$ in Equation (5) has the form $L(\theta) = \nabla J(\theta)$. In the SPSA algorithm, the quantity $(L(\theta_n) + M_{n+1})$ in Equation (5) is replaced by $Y_n = (Y_{n,1}, \dots, Y_{n,N})^T$ with

$$Y_{n,i} = \frac{J(\theta_n + c_n \Delta_n) - J(\theta_n - c_n \Delta_n)}{2c_n \Delta_{n,i}} + \frac{\xi_{n+1,i}^+ - \xi_{n+1,i}^-}{2c_n \Delta_{n,i}}, \quad (10)$$

where the random vectors $(\xi_{n+1,i}^+ - \xi_{n+1,i}^-)$, $n \geq 0$ are assumed to form a martingale difference sequence. Further, $\Delta_{n,i}$, $i = 1, \dots, N$ are independent of the above random vectors.

An interesting observation here is that while in FDSA, given θ_n , the estimate of $\nabla J(\theta_n)$, ignoring the noise term $(\xi_{n+1,i}^+ - \xi_{n+1,i}^-)/2c_n$ (Eq. 8), is deterministic; it is not so in SPSA. The randomness in the gradient estimate (even without the noise term) in SPSA arises due to the randomness in the search direction that in turn, is caused by the random perturbations Δ_n . Thus, even if the noise term in the SPSA estimate (Eq. 10) $((\xi_{n+1,i}^+ - \xi_{n+1,i}^-)/2c_n \Delta_{n,i})$ is not present, one would still be in the stochastic optimization

setting because of the randomness in search direction. This aspect was briefly discussed in the first two sections of this article. Note that Equation (10) has both terms stochastic, while this is not the case with Equation (5) where the term multiplying $a(n)$ has a deterministic part ($L(\theta_n)$, given θ_n) and a stochastic part (M_{n+1}). Through suitable Taylor series expansions, however (see Eq. 11), the first term on the RHS of Equation (10) can be further split into a deterministic term (i.e., precisely the gradient of J) and a stochastic term (together with an asymptotically diminishing error). The latter stochastic term can be combined with the second stochastic term in Equation (10) to obtain a dominant stochastic term, that again turns out to be a martingale difference. We describe the SPSA algorithm in detail below.

The SPSA Algorithm.

Step 0 (Initialize): Set $\theta_0 = (\theta_{0,1}, \dots, \theta_{0,N})^T$ and obtain $\Delta_0 = (\Delta_{0,1}, \dots, \Delta_{0,N})^T$, where $\Delta_{0,i}$ are independent samples obtained according to $\Delta_{0,i} = \pm 1$ w.p. 1/2, $i = 1, \dots, N$. Select parameter sequences $\{a_n, n \geq 0\}$ and $\{c_n, n \geq 0\}$. Make two sample measurements $Y_0^+ = J(\theta_0 + c_0 \Delta_0) + \xi_1^+$ and $Y_0^- = J(\theta_0 - c_0 \Delta_0) + \xi_1^-$ with parameters $(\theta_0 + c_0 \Delta_0)$ and $(\theta_0 - c_0 \Delta_0)$, respectively. Select a large finite integer M . Set $n := 0$.

Step 1: Update parameter $\theta_n = (\theta_{n,1}, \dots, \theta_{n,N})^T$ according to: For $i = 1, \dots, N$,

$$\theta_{n+1,i} = \theta_{n,i} - a_n \left(\frac{Y_n^+ - Y_n^-}{2c_n \Delta_{n,i}} \right).$$

Step 2: Set $n := n + 1$.

- If $n < M$, obtain new samples $\Delta_{n,i}$ independently according to $\Delta_{n,i} = \pm 1$ w.p. 1/2. Form the vectors $\theta_n = (\theta_{n,1}, \dots, \theta_{n,N})^T$ and $\Delta_n = (\Delta_{n,1}, \dots, \Delta_{n,N})^T$. Make two measurements $Y_n^+ = J(\theta_n + c_n \Delta_n) + \xi_{n+1}^+$ and $Y_n^- = J(\theta_n - c_n \Delta_n) + \xi_{n+1}^-$, respectively. Go to Step 1.

- If $n = M$, terminate algorithm and output $\theta_n = (\theta_{n,1}, \dots, \theta_{n,N})^T$ as the final value of the parameter.

We assume above that the algorithm terminates after M iterations. Asymptotic convergence is then achieved as $M \rightarrow \infty$. More sophisticated stopping criteria may however be used as well. Here the parameters a_n, c_n are such that $a_n, c_n \rightarrow 0$ as $n \rightarrow \infty$. Because of the presence of c_n in the denominator of the martingale difference term, one requires here that $\sum_n \left(\frac{a_n}{c_n} \right)^2 < \infty$ in addition to $\sum_n a_n = \infty$, that is similar to the first condition in Equation (4). The former condition above is however stronger than the second condition in Equation (4) and is required in order to use the martingale convergence theorem (Theorem 11, Appendix C of Ref. 12) to show that an associated martingale sequence converges. The above assumption on the parameters $a_n, c_n, n \geq 0$ has been made in Ref. 3. In Ref. 18, a relaxation is made whereby it is assumed that $a_n, c_n \rightarrow 0$ as $n \rightarrow \infty$ and that $\sum_n a_n = \infty$, $\sum_n a_n^p < \infty$ for some $p \in (1, 2]$. Typically $a_n, c_n, n \geq 0$ can be chosen according to $a_n = a/(A + n + 1)^\alpha$ and $c_n = c/(n + 1)^\gamma$, for $a, A, c > 0$. The suggested values of α and γ given in Refs 36 and 37 are 1 and 1/6 respectively. In Ref. 38, it is observed that the choices $\alpha = 0.602$ and $\gamma = 0.101$ perform better in practical settings.

The reason why SPSA is a valid gradient algorithm is easy to see from Taylor expansions of $J(\theta_n + c_n \Delta_n)$ and $J(\theta_n - c_n \Delta_n)$ around the parameter θ_n as under

$$\begin{aligned} J(\theta_n + c_n \Delta_n) &= J(\theta_n) + c_n \Delta_n^T \nabla J(\theta_n) \\ &\quad + \frac{c_n^2}{2} \Delta_n^T \nabla^2 J(\theta_n) \Delta_n + o(c_n^2), \\ J(\theta_n - c_n \Delta_n) &= J(\theta_n) - c_n \Delta_n^T \nabla J(\theta_n) \\ &\quad + \frac{c_n^2}{2} \Delta_n^T \nabla^2 J(\theta_n) \Delta_n + o(c_n^2). \end{aligned}$$

From the above two equations, we obtain

$$\begin{aligned} \frac{J(\theta_n + c_n \Delta_n) - J(\theta_n - c_n \Delta_n)}{2c_n \Delta_{n,i}} &= \nabla_i J(\theta_n) \\ &\quad + \sum_{j=1, j \neq i}^N \frac{\Delta_{n,j}}{\Delta_{n,i}} \nabla_j J(\theta_n) + o(c_n). \end{aligned} \quad (11)$$

Now observe that the conditional expectation of the estimate given the parameter θ_n equals

$$\begin{aligned} E \left[\frac{J(\theta_n + c_n \Delta_n) - J(\theta_n - c_n \Delta_n)}{2c_n \Delta_{n,i}} \mid \theta_n \right] \\ = \nabla_i J(\theta_n) + o(c_n), \end{aligned} \quad (12)$$

from the properties on the perturbations $\Delta_{n,i}$. Thus, while the search direction is randomly chosen and need not follow a descent path in a given update, the algorithm is seen to follow asymptotically the right path.

In Ref. 39, a one-measurement version of SPSA has been presented. The simulation here is run with the parameter $\theta_n + c_n \Delta_n$ with Y_n having the form

$$Y_{n,i} = \frac{J(\theta_n + c_n \Delta_n)}{c_n \Delta_{n,i}} + \frac{\xi_{n+1}^+}{c_n \Delta_{n,i}}, \quad (13)$$

$i = 1, \dots, N$ in place of Equation (10) with Δ_n as before. A calculation similar to the two-measurement SPSA, based on a Taylor series expansion, shows that

$$\begin{aligned} \frac{J(\theta_n + c_n \Delta_n)}{c_n \Delta_{n,i}} &= \frac{J(\theta_n)}{c_n \Delta_{n,i}} + \nabla_i J(\theta_n) \\ &+ \sum_{j=1, j \neq i}^N \frac{\Delta_{n,j}}{\Delta_{n,i}} \nabla_j J(\theta_n) \\ &+ \frac{c_n}{2} \frac{\Delta_n^T \nabla^2 J(\theta_n) \nabla_n}{\Delta_{n,i}} + o(c_n). \end{aligned} \quad (14)$$

As has been noted in Ref. 39 and other references, for instance Ref. 40, that even while a similar conclusion as Equation (12) can be seen to be valid for the one-measurement version, its performance primarily suffers because of the presence of the first term on the RHS of Equation (14) as the factor c_n in the denominator there can make the term excessively large for large n (because $c_n \rightarrow 0$ as $n \rightarrow \infty$). In particular, two-simulation SPSA (Eq. 10) has been seen to be much superior in comparison to one-simulation SPSA (Eq. 13).

A one-sided version of SPSA with two measurements has been considered in Ref. 18. Here the two simulations are

run with parameters $\theta_n + c_n \Delta_n$ and θ_n , respectively, and Y_n above has the form

$$Y_{n,i} = \frac{J(\theta_n + c_n \Delta_n) - J(\theta_n)}{c_n \Delta_{n,i}} + \frac{\xi_{n+1}^+ - \xi_{n+1}^-}{c_n \Delta_{n,i}}, \quad (15)$$

$i = 1, \dots, N$ with Δ_n as before. A Taylor series expansion here shows that a second-order term that cancels in the case of two-sided SPSA, remains in the one-sided version. This term vanishes as $n \rightarrow 0$, however, it adds slightly to the overall bias in the estimate. The two-sided form, Equation (10) is the most studied and used in applications.

It is interesting to note that in the expression (Eq. 10) [also Eqs (15) and (13)] for the $Y_{n,i}$, the numerator is the same across all i , $i = 1, \dots, N$, while the denominator has a quantity $\Delta_{n,i}$ that depends on i . This is unlike FDSA where the denominator is the same while the numerator is different for different i , see Equations (8) and (9). Thus, in going from FDSA to SPSA, the complexity in estimating the gradient shifts (in a way) from the numerator of the estimator to its denominator. It should be noted that simulating N independent symmetric Bernoulli random variables, is in general, far less computationally expensive than obtaining $2N$ or $(N+1)$ objective function measurements or simulations, particularly when N is large. It has been seen from both, theory and experiments [3,30,41], that two-sided, two-measurement SPSA is computationally far superior to FDSA. In Ref. 3, asymptotic normality results for SPSA and FDSA are used to establish the relative efficiency of SPSA. The asymptotic analysis for the R-M algorithm can be adapted to prove a.s. convergence of the iterates in the SPSA algorithm [3]. Assuming that there is a unique globally asymptotically stable equilibrium θ^* for the associated ODE (i.e., a global minimum for the basic algorithm), the asymptotic normality result in Ref. 3 essentially says that

$$n^{r/2}(\theta_n - \theta^*) \xrightarrow{D} N(\mu, \Sigma)$$

as $n \rightarrow \infty$, where $\xrightarrow{D}$ denotes convergence in distribution, $N(\mu, \Sigma)$ is a multivariate Gaussian with mean μ and covariance matrix Σ that depends on the Hessian at θ^* . In general, $\mu \neq 0$. The quantity r depends upon the choice of the gain sequences $a_n, c_n, n \geq 0$.

Many interesting analyses of the SPSA algorithm have been reported in the literature. In Ref. 3, the above asymptotic normality result is used to argue the relative asymptotic efficiency of SPSA over FDSA. In particular, it is argued that SPSA results in an N -fold computational savings over FDSA. In Ref. 18, a projected version of SPSA, where the projection region is gradually increased, has been presented. This is a novel approach to take care of the issue of iterate stability in general. In Refs 42 and 43, application of SPSA for optimization in the case of nondifferentiable functions is considered. A detailed analysis of SPSA under general conditions can also be found in Ref. 44. An analysis of SPSA and FDSA when common random numbers are used in the simulations is given in Ref. 32. Different ways of gradient estimation in SPSA using past measurements have been reported in Refs 45 and 46. In Ref. 47, iterate averaging for stability of the SPSA recursions and improved algorithmic behavior is explored. A case of weighted averaging of the Kiefer–Wolfowitz and SPSA iterates is considered in Ref. 48. In Refs 49 and 50, SPSA is proposed for use as a global search algorithm. In Ref. 36, SPSA is compared with a two-sided smoothed functional algorithm (see the section titled “The Smoothed Functional Algorithm”) and it is found that SPSA is the better of the two algorithms. This algorithm is referred to as *random directions stochastic approximation* (RDSA) in Ref. 36. In Ref. 38, the general technique for implementing SPSA and the choice of gain sequences is discussed.

The SPSA algorithm has evoked significant interest due to its good performance, ease of implementation, and wide applicability. Moreover, it is observed to be scalable in that the computational effort does not increase enormously with parameter dimension. This is not the case with FDSA (see for instance, the experiments in Ref. 30). In the next two sections, we shall

review some of the recent research directions related to the SPSA algorithm and many of the various applications, in fact application areas/domains where the original algorithm and also its variants have been applied and found useful.

VARIATIONS TO THE BASIC SCHEME

In this section, we describe some of the variations to the basic scheme.

Multitimescale Algorithms

Consider the following variation to the R–M scheme:

$$\theta_{n+1} = \theta_n + a_n(f(\theta_n, \omega_n) + M_{n+1}^1), \quad (16)$$

$$\omega_{n+1} = \omega_n + b_n(g(\theta_n, \omega_n) + M_{n+1}^2). \quad (17)$$

Here, Equations (16) and (17) are coupled updates that involve a parameter ‘ ω ’ in addition to θ . Also, $M_{n+1}^1, M_{n+1}^2, n \geq 0$ are certain martingale difference sequences w.r.t. the coupled recursions. Further, $a_n, b_n, n \geq 0$ are two step-size schedules that satisfy the regular step-size conditions (Eq. 4). In addition, we also require $a_n/b_n \rightarrow 0$ as $n \rightarrow \infty$. An example of $a_n, b_n, n \geq 0$ is $a_n = c_1/(n+1), b_n = c_2/(n+1)^\alpha$, for any $c_1, c_2 > 0$ and $\alpha \in (0.5, 1)$. Recursions governed by $\{a_n\}$ would appear to be quasi-static when viewed from the “timescale of $\{b_n\}$ ” while from the “timescale of $\{a_n\}$,” the other recursions would appear to be equilibrated. Thus recursions (Eq. 16) are called the “slower recursions” while recursions 17 are the “faster ones.” A general analysis of two-timescale stochastic approximation using an ODE approach is provided in Ref. 51; see also Ref. 12.

Multitimescale algorithms are helpful in cases when in between two successive updates of the algorithm, one typically has to perform an inner-loop procedure recursively until it converges. Thus, one would in practice, have to wait for a long time before updating the algorithm once. By using a multitimescale algorithm as in Equations (16) and (17), both recursions (for

the inner and outer loops) can run together, and convergence to the desired point can be achieved. Key application areas where this procedure has been successfully applied are simulation optimization and adaptive control. We review these application areas in the next section. There is another reason why multitimescale algorithms are interesting. In Ref. 52, averaging of stochastic approximation iterates in the case of one-timescale algorithms such as Equation (5) has been seen to improve the rate of convergence. The same procedure can be accomplished using a two-timescale algorithm such as Equations (16) and (17) wherein the “averaging” is performed along the faster timescale.

In Ref. 53, a smoothed version of SPSA that is seen to improve performance is presented. The idea there is similar to the averaging in Ref. 52 and the resulting algorithm has a multitimescale character. In Refs 54 and 55, the step-sizes a_n , $n \geq 0$ are adaptively set according to the objective function value obtained. Since the update direction in SPSA is random, a move in the descent direction in Refs 54 and 55 is rewarded by a slightly higher step-size in the next update step. A move in the ascent direction, on the other hand, attracts a penalty. Moreover, if the objective function value gets worse, a certain blocking mechanism is enforced whereby starting from the previous estimate, a new gradient evaluation is made with a reduced step-size a_n . The procedure of Refs 54 and 55 is performed for the smoothed version of SPSA making the overall scheme again of the multitimescale type.

The convergence theory of multitimescale methods has been dealt with in detail in Refs 11, 12, 28–30, 34, 40, 51, 56, and 57 and many other references.

Deterministic Perturbations SPSA

In the basic SPSA framework, the perturbations $\Delta_i(n)$ were considered to be random variables. In Ref. 58, certain deterministic conditions on the perturbation vectors and noise sequences in SPSA are obtained under which the algorithm is shown to converge. In Refs 40 and 59, certain deterministic constructions for the perturbations in SPSA have

been described. Each deterministic construction in the above references relies on obtaining a suitable set in which the $\{\pm 1\}^N$ -valued vectors Δ_n take values in, and assigning in a cyclic manner, the elements in the set to the vectors Δ_n at each of the instants $n \geq 0$.

It is observed in Ref. 40 that the perturbation vectors in a deterministic construction (assuming they are $\{\pm 1\}^N$ -valued) should satisfy the following property in the case of two-sided SPSA (Eq. 10): There exists an integer $P > 1$ such that for all $i, j \in \{1, \dots, N\}$, $i \neq j$ and for any $s \geq 1$,

$$\sum_{n=s}^{s+P} \frac{\Delta_i(n)}{\Delta_j(n)} = 0. \quad (18)$$

For one-measurement SPSA, one requires the following property in addition to Equation (18): there exists a $P > 1$ such that for every $k \in \{1, \dots, N\}$ and any $s \geq 1$,

$$\sum_{n=s}^{s+P} \frac{1}{\Delta_k(n)} = 0. \quad (19)$$

The idea behind using deterministic perturbations is to try and reduce the bias in the gradient estimates by cancelling bias terms in a regular/deterministic manner.

One of the constructions in Ref. 40 that we briefly describe is observed to significantly improve the performance of one-simulation SPSA (Eq. 13). The construction is via “normalized Hadamard matrices.” Let $K = \lceil \log_2(N+1) \rceil$. Obtain a $2^K \times 2^K$ -matrix H_{2^K} in a recursive manner as follows:

$$H_2 = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$$

$$\text{and } H_{2^l} = \begin{bmatrix} H_{2^{l-1}} & H_{2^{l-1}} \\ H_{2^{l-1}} & -H_{2^{l-1}} \end{bmatrix}, \quad l > 1.$$

Having obtained H_{2^K} , form a new matrix Q of dimension $2^K \times N$ by removing the first column of H_{2^K} and selecting any N of its remaining columns. Let $Q(1), \dots, Q(2^K)$ denote the rows of Q . Now set $\Delta_0 = Q(1)$, $\Delta_1 = Q(2), \dots, \Delta_{2^K-1} = Q(2^K)$, $\Delta_{2^K} = Q(0)$ etc. Thus, the perturbations are obtained by cyclically passing through the rows of Q . SPSA with deterministic perturbations

has been successfully applied in some applications [60–62].

Higher-Order SPSA

The algorithms FDSA and SPSA described in the previous two sections are gradient algorithms (see the section titled “Algorithms for Local Search”). Adaptive stochastic approximation algorithms based on computing the Hessian (in addition to the gradient) estimates typically require many more samples of the objective function than those that estimate only the gradient. For instance, in Ref. 37, the Hessian is estimated using finite differences that are in turn based on finite-difference estimates of the gradient. This requires $O(N^2)$ samples of the objective function at each update epoch. In Ref. 63, an adaptive multivariate version of the Robbins-Monro [1] algorithm is obtained for the case where the objective function gradients are known and the Hessian is estimated using finite gradient differences.

Recently in Ref. 64, a simultaneous perturbation version of Newton’s algorithm was presented. The Hessian estimates here are obtained using four objective function samples at each update epoch in cases where the gradient estimates are not known, and three samples in cases where these are known. This is achieved by using two independent perturbation sequences with random variables in each assumed bounded, zero-mean, symmetric, having a common distribution and mutually independent of one another, and with finite inverse moments. This method is an extension of regular SPSA [3] that estimates only the gradient and requires only one perturbation sequence. The Hessian updates are projected to the set of positive definite matrices (necessary for a *descent* direction). In Ref. 65, a similar algorithm is presented where the projected Hessian is replaced by the geometric mean of the projected eigenvalues of it. Certain enhancements to the Jacobian or Hessian estimates [64] that improve their quality have recently been presented in Ref. 66.

In Ref. 11, four adaptive multitimescale Newton-based algorithms in the setting of simulation optimization have been proposed.

These are all based on the simultaneous perturbation method and require four, three, two, and one simulation(s) respectively. The four-simulation algorithm has a similar Hessian estimate as the one in Ref. 64. In addition, different estimates for the Hessian have been derived in Ref. 11. The algorithms in Ref. 11 are developed in the setting of simulation optimization and use three timescales where on the fastest scale the Hessian is averaged, on the middle timescale data averaging is done, and on the slowest scale, the optimization parameter θ is updated. We briefly describe below the algorithm of Ref. 64.

Let $\Delta_{n,k}, \hat{\Delta}_{n,k}, k = 1, \dots, N, n \geq 0$ denote the two independent perturbation sequences. Let $\Delta_n = (\Delta_{n,1}, \dots, \Delta_{n,N})^T$ and $\hat{\Delta}_n = (\hat{\Delta}_{n,1}, \dots, \hat{\Delta}_{n,N})^T$, respectively. Consider four independent simulations or function measurements with parameters $(\theta_n + c_n \Delta_n), (\theta_n - c_n \Delta_n), (\theta_n + c_n \Delta_n + \hat{c}_n \hat{\Delta}_n)$, and $(\theta_n - c_n \Delta_n + \hat{c}_n \hat{\Delta}_n)$, respectively. Here $c_n, \hat{c}_n \rightarrow 0$ as $n \rightarrow \infty$. The estimate of the (k, l) th component of the Hessian ($\hat{H}_n$) has the form $\hat{H}_n^{k,l} = (4c_n \hat{c}_n)^{-1} [(\Delta_{n,k} \hat{\Delta}_{n,l})^{-1} + (\Delta_{n,l} \hat{\Delta}_{n,k})^{-1}] [(J(\theta_n + c_n \Delta_n + \hat{c}_n \hat{\Delta}_n) + \xi_{n+1}^{++}) - (J(\theta_n + c_n \Delta_n) + \xi_{n+1}^+) - (J(\theta_n - c_n \Delta_n + \hat{c}_n \hat{\Delta}_n) + \xi_{n+1}^{+-}) + (J(\theta_n - c_n \Delta_n) + \xi_{n+1}^-)]$, $k, l = 1, \dots, N$. Here, $\xi_{n+1}^+, \xi_{n+1}^-, \xi_{n+1}^{++}$ and ξ_{n+1}^{+-} , $n \geq 0$ are certain martingale difference sequences that are in general independent of each other. Then

$$\theta_{n+1} = \theta_n - a_n \bar{H}_n^{-1} \left(\frac{J(\theta_n + c_n \Delta_n) - J(\theta_n - c_n \Delta_n)}{2c_n} + \frac{\xi_{n+1}^+ - \xi_{n+1}^-}{2c_n} \right) \Delta_n^{-1}, \quad (20)$$

$$H_n^1 = \frac{n}{n+1} H_{n-1}^1 + \frac{1}{n+1} \hat{H}_n, \quad (21)$$

$$\bar{H}_n = f_n(H_n^1), \quad (22)$$

$n \geq 0$. Here $\Delta_n^{-1} = (\Delta_{n,1}^{-1}, \dots, \Delta_{n,N}^{-1})^T$. Also, f_n is a map that projects the Hessian update to the set of positive definite matrices. In practice, performing this step and taking inverse of the projected Hessian matrix are time-consuming operations, more so when N is large. The Jacobi version of the algorithm [11,64], whereby only the diagonal entries of the Hessian are updated and the off-diagonal

terms are set to zero, is an efficient way to use some of the Hessian information to improve algorithm behavior while the computational effort increases only marginally (over gradient SPSA) in doing so. This procedure is usually recommended for large N [11,64]. Here a_n , c_n , and $\hat{c}_n$ can be chosen according to $a_n = a/(n+A)^\alpha$, $c_n = c/n^\gamma$ and $\hat{c}_n = \hat{c}/n^\gamma$, respectively, with $a, c, \hat{c} > 0$ and $A \geq 0$. In Ref. 64, the values recommended for α and γ are $\alpha = 0.602$ and $\gamma = 0.101$, respectively.

The Smoothed Functional Algorithm

In Ref. 67, a one-simulation “smoothed functional (SF)” algorithm was presented. The idea there is to convolve the gradient of the objective function with a multivariate Gaussian density and then by an appropriate integration by parts argument, shows that it is the same as a convolution of the objective itself with a scaled Gaussian. Hence, by slowly diminishing the variance parameter in the Gaussian, one recovers the desired gradient using one simulation. This algorithm is called the *smoothed functional algorithm* because the procedure of convolving with a Gaussian smooths the objective. We explain the key idea here. Given a constant $\beta > 0$, let

$$D_\beta J(\theta) \triangleq \int G_\beta(\theta - \eta) \nabla_\eta J(\eta) d\eta \quad (23)$$

represent the convolution of the gradient of average cost ($J(\cdot)$) with the N -dimensional multivariate normal p.d.f.

$$G_\beta(\theta - \eta) = \frac{1}{(2\pi)^{N/2} \beta^N} \times \exp\left(-\frac{1}{2} \sum_{i=1}^N \frac{(\theta_i - \eta_i)^2}{\beta^2}\right),$$

where $\theta \triangleq (\theta_1, \dots, \theta_N)^T$ and $\eta = (\eta_1, \dots, \eta_N)^T$, respectively. Integrating by parts in Equation (23), it is easy to see that

$$\begin{aligned} D_\beta J(\theta) &= \int \nabla_\theta G_\beta(\theta - \eta) J(\eta) d\eta \\ &= \int \nabla_\eta G_\beta(\eta) J(\theta - \eta) d\eta. \end{aligned} \quad (24)$$

One can easily check that $\nabla_\eta G_\beta(\eta) = \frac{-\eta}{\beta^2} G_\beta(\eta)$ [34,56]. Substituting $\eta' = \frac{\eta}{\beta}$ in Equation (24), one then obtains

$$D_\beta J(\theta) = \frac{1}{\beta} \int -\eta' G_1(\eta') J(\theta - \beta\eta') d\eta', \quad (25)$$

where $G_1(\eta') = G_\beta(\eta')|_{\beta=1}$. Replacing $-\eta'$ by η , one gets the following SF estimate for the gradient [67]:

$$\nabla J(\theta_n) \approx \frac{1}{\beta} \frac{1}{M} \sum_{n=1}^M \eta_n J(\theta_n + \beta\eta_n), \quad (26)$$

for $\beta > 0$ small and M large. Here η_n is an N -vector of independent $N(0, 1)$ -distributed random variables.

The following symmetric two-sided finite-difference form of SF estimates has been studied in Refs 34, 36, 68, and 69:

$$\begin{aligned} \nabla J(\theta_n) &\approx \frac{1}{\beta} \frac{1}{M} \sum_{n=1}^M \eta_n (J(\theta_n + \beta\eta_n) \\ &\quad - J(\theta_n - \beta\eta_n)), \end{aligned} \quad (27)$$

for small β and large M as before. The balanced estimate (Eq. 27) has less bias as compared to Equation (26). This can be seen using suitable Taylor series expansions as in the case of the SPSA estimates in the section titled “Simultaneous Perturbation Stochastic Approximation.” A detailed convergence analysis of this algorithm in the multiscale setting is presented in Ref. 34.

The SF algorithm falls within the category of finite-difference methods, one that is also based on the idea of random perturbations. In Ref. 36, it is observed that SF is not as computationally efficient as SPSA. Further, generating Gaussian random variables requires more computational effort than generating Bernoulli random variables. However, the objective smoothing that results because of the convolution can, in fact, help the algorithm to converge to a global minimum. This fact has been observed in Ref. 68. In experiments on an admission control problem with dependent service times [70], where the objective function is seen to

be almost flat with a sharp dip in between, it is observed that many times SF converges to the global minimum. However, there is no theory currently available that proves convergence of SF to a global minimum. It would be interesting if guidelines can be suggested for guaranteed convergence of this and other algorithms to a global minimum. Perturbations in SF need not be confined to normal random variables but more generally, the uniform and Cauchy distributions can also be used.

The above ideas have been explored further in Ref. 34 and two SF estimates for the Hessian have been derived for the first time. Using these estimates for the Hessian, and the above estimates for the gradient, two Newton SF algorithms have been developed in Ref. 34. Thus one of the algorithms there requires only one measurement or simulation (with parameter $\theta_n + \beta\eta_n$) while the other requires two of them (with parameters $\theta_n + \beta\eta_n$ and $\theta_n - \beta\eta_n$, respectively). The Hessian estimates have been derived using the (above) integration by parts argument twice. An advantage with this approach is that the same simulations that are used to estimate the gradients are also used to estimate the Hessians. Thus, with a small increase in computational effort (using the Jacobi case say), one obtains a good second-order algorithm that has the potential to converge to a global minimum.

Optimization under Inequality Constraints

We consider here the following variation to the basic problem (Eq. 1).

$$\begin{aligned} \text{Find } \theta^* \text{ for which } J(\theta^*) = \min_{\theta \in C} \{J(\theta) \mid G_i(\theta) \\ \leq \alpha_i, \quad i = 1, \dots, p\}. \end{aligned} \quad (28)$$

Here $G_i(\cdot)$ and $\alpha_i, i = 1, \dots, p$ are certain prescribed functions and constants, respectively, that constitute the functional constraints. Such problems arise for instance in communication networks, where the objective function J could correspond to the negative of the average throughput (because the problem is one of minimization and not maximization, see

the first section), and a constraint may specify that the average delay must be below a threshold. Another constraint may similarly specify that the probability of packet loss during transmission must not be more than a small constant, say 0.01.

There is a vast literature on optimization problems with functional constraints. More recently, SPSA has been applied on these problems as well. In Ref. 71, a constrained optimization setting in which the inequality constraints are explicit functions of the optimization parameters is considered and an SPSA-based algorithm is presented in which the parameter is projected to the constraint set after each update. In Ref. 72, the penalty function approach is used together with SPSA for an optimization problem with inequality constraints. As with Ref. 71, it is assumed in Ref. 72 that the constraint functions are analytically known as *functions of the underlying parameter*.

For a constrained optimization problem on a discrete set, certain penalty function-based SPSA algorithms are presented in Ref. 73 that differ from each other in the manner in which the projection is done in order to obtain a parameter within the discrete set of parameters. Applications to a problem of resource allocation are also studied in Ref. 73.

In Ref. 74, a problem of optimization under inequality constraints is considered, where both the objective and constraint functions are certain long-run averages. Thus, neither the objective nor the constraints are known analytically and so projection after each parameter update to the constraint region is ruled out. A Lagrange multiplier approach is used in Ref. 74 and the problem is formulated in the multitimescale stochastic approximation framework. Algorithms based on (gradient and Newton) SPSA and SF are presented for this problem in Ref. 74. Experiments on a communication network scenario show good performance using these algorithms.

APPLICATIONS OF SPSA

SPSA has been successfully applied in a wide range of applications and in a

variety of disciplines such as electrical and communications engineering, mechanical engineering, industrial engineering, civil engineering, management science, physics, operations research, chemical engineering, and biology. We describe here some of the representative work on applications of SPSA and algorithms developed along the lines of SPSA. Reference 75 provides an up-to-date web site on SPSA that contains many of the papers included in this survey. This web site also includes many other papers on SPSA that are not included here and which are by no means any less interesting.

Discrete Parameter Optimization

It is well known that discrete optimization problems are hard combinatorial problems. SPSA, which is primarily a continuous optimization algorithm, has been successfully adapted in many applications involving discrete optimization problems [70,76–80]. In Refs 70, 76 and 77, discrete parameter SPSA has been applied on problems in admission control in communication networks.

Estimating the Fisher Information Matrix

There has been work on using the simultaneous perturbation approach for estimating the Fisher information matrix that is widely used in system identification problems. Reference 81 is an early work on natural gradient estimation using SPSA, where the Fisher information matrix plays a key role. In Ref. 82, a resampling based method to estimate the Fisher information matrix has been proposed. In Ref. 83, an extension to the approach in Ref. 82 is presented for the case when parts of the matrix are known *a priori*.

Simulation Optimization

Simulation optimization refers to a class of techniques that are applicable when the system model is not known, however, the system can be simulated and the outcomes from the simulation can be used to optimize the system parameters [28,30,33]. Most often, one is interested in optimizing an objective function $J(\cdot)$ that is a long-run average quantity.

For instance, in a queueing system, think of minimizing the long-run average waiting time of a customer. A difficulty with such an objective function is that in order to use an algorithm such as SPSA, one needs to know the value of $J(\theta_n)$ at each update θ_n of the parameter. Many of the perturbation analysis-based approaches [23,25–27] use only one simulation but require strict regularity conditions on the system and performance functions. Moreover, quite often parameter updates here are performed only at regeneration epochs of a certain underlying process.

In Refs 28 and 29, two-timescale stochastic approximation (see section titled “Multitimescale Algorithms”) is used for this purpose where on the faster scale, data is aggregated and on the slower one, the parameter is updated. The FDSA gradient estimates were used in Refs 28 and 29. In Ref. 30, SPSA-based estimates were used that were seen to significantly improve performance over the algorithms in Refs 28 and 29. More recently, in Refs 11 and 34, Newton-based algorithms have been developed in the multitimescale framework. In Ref. 69, one of the algorithms of Ref. 34 has been applied for a problem of optimal trajectory estimation in parameterized stochastic differential equations.

Optimal Control and Reinforcement Learning

There has been significant work in the areas of optimal control and reinforcement learning where SPSA has been applied. For instance, in Refs 84 and 85 the SPSA algorithm has been applied for solving infinite-horizon Markov decision processes (MDPs) when model information is not known, under the discounted cost and long-run average cost criteria respectively. In Refs 86 and 87, the finite-horizon MDP problem is similarly considered. The case when the underlying state-space of the system could be potentially large is also considered because of which certain feature-based representations are used. In Ref. 62, a reinforcement learning algorithm using deterministic perturbations SPSA has been developed and studied for the problem of optimal mortgage refinancing. In Ref.

88, certain multitimescale Q-learning algorithms in the area of reinforcement learning have been developed. In Ref. 60, an algorithm for long-run average cost control of Markov chains conditioned on rare events has been developed. Also, in Ref. 89, two actor-critic algorithms for hierarchical control of Markov decision processes have been developed. All the above algorithms are based on some form of SPSA (with randomized or deterministic perturbations and one or two simulations). For a problem of adaptive control, Spall and Cristion [90] use SPSA and show convergence for a time-varying objective. An application of SPSA in an optimal control setting has also been studied in Ref. 91.

Communication and Wireless Networks

SPSA has been applied in problems of control and optimization in communication networks. In Ref. 57, SPSA has been applied for finding optimal policies in available bit rate (ABR) service in asynchronous transfer mode (ATM) networks. In the context of the random early detection (RED) scheme for the Internet, Vaidya and Bhatnagar [92] developed and applied a variant of SPSA that works with only the sign of the objective (this algorithm can be of independent interest in communications engineering where it is desirable to make decisions based on one or at most a few bits of information). In Ref. 61, a higher-order-SPSA-based algorithm has been applied for tuning RED parameters. This algorithm shows better performance than most well-known algorithms in the RED literature [61]. The problem of admission control using SPSA has been studied in Refs 70, 76, and 77. Application of an SPSA-based control scheme in dynamic routing has been studied in Ref. 88. In Ref. 93, SPSA has been applied for finding an optimal slot assignment policy in bluetooth wireless networks. In Ref. 94, a measurement-based routing algorithm derived from SPSA has been proposed for several unicast sessions. In Ref. 95, SPSA has been applied on a problem of optimal placement of acoustic sensors for a system.

Neural Networks

SPSA has been applied in many applications related to neural networks. For instance, in

Ref. 96, SPSA is used to train the weights of a neural network controller for controlling the light timings at a traffic junction in a traffic network. A recursive learning scheme for recurrent neural networks using SPSA has been proposed in Ref. 97. In Ref. 98, an on-line training algorithm based on SPSA is used in a neural tracking control system. A modified SPSA algorithm with certain adaptive gain sequences and smoothing of iterates across recursions is used in the design of a neural network controller in Ref. 54. In Ref. 99, SPSA is used for training in robust neural network tracking controllers in nonlinear systems. In Ref. 53, a smoothed SPSA estimation procedure has been used for modeling the underlying control mechanism in a neural network that is used for the control of dynamic systems [100]. In Ref. 101, SPSA is applied for cascade learning in single hidden layer neural networks. Certain modifications to the SPSA algorithm using gradient smoothing and adaptive gains with an application to training neural networks have been studied [55].

Pattern Recognition and Image Processing

SPSA has been applied in pattern recognition and signal/image processing applications as well. In Ref. 102, an SPSA-based algorithm for feature selection in a nearest neighbor classifier is proposed. In Ref. 103, SPSA is applied for feature-relevance estimation in video retrieval applications. In Ref. 104, a combination of Tsallis entropy and SPSA is used to register images efficiently. In Ref. 105, SPSA has been successfully applied for efficient image restoration. A nonlinear inversion procedure for images has also been proposed [106].

Traffic Optimization

SPSA has been applied to various aspects of traffic optimization, for both airline and land-based traffic. In Ref. 107, the problem of minimizing airtraffic delay is treated as a constrained optimization problem and a penalty function approach is used together with SPSA. In Ref. 108, an optimal gate-holding schedule to minimize cost of delays and air congestion in airtraffic networks is

obtained using SPSA. In Ref. 109, an application to aerodynamic design using SPSA is studied. In Ref. 110, an SPSA-based model has been proposed for the problem of seat allocation in airlines.

In Ref. 111, SPSA is used in a function approximation-based scheme to control the timing of signals in a traffic network. In Ref. 112, SPSA is applied to find optimal traffic signal timings for light rail transit (LRT) vehicles, see also Ref. 113 where SPSA is used in an application of traffic signal control as well. In Ref. 114, SPSA with a perturbation distribution over a smaller set than the one obtained from Bernoulli sequences, is used to optimize fuel consumption in engine operations.

Other Interesting Applications

In some other applications, SPSA has been applied in game programming [115]. In Ref. 116, an implementation of SPSA on an analog very large scale integration (VLSI) chip has been discussed. In Ref. 117, an SPSA-based approach is used for dynamic optimization in systems requiring continuous measurements. In Ref. 118, an application of SPSA to electrocardiogram (ECG) analysis has been studied. In Ref. 119, a “system of systems” view of military tasks/operations is presented and the first- and second-order SPSA algorithms are used for optimizing costs under given constraints. In Ref. 41, FDSA and SPSA have been applied for on-line estimation of parameters in nonlinear/non-Gaussian state-space models with particle filters. In Ref. 120, a simulation optimization framework with SPSA estimates has been considered for inventory control applications in semiconductor manufacturing. In Ref. 121, SPSA has been applied for automatic controller tuning for electrohydraulic valves. In Ref. 122, SPSA has been applied in the modeling of batch animal cell cultures. In Ref. 123, a “grid infrastructure” is used for determining the optimal locations of oil wells.

The applications described above, apart from being interesting in themselves, also illustrate the fact that SPSA and SPSA-type algorithms are widely used stochastic optimization procedures that have been successfully applied in a variety of disciplines.

SINGLE MACHINE SCHEDULING

NEIL GEISMAR

Department of Information and
Operations Management, Mays
Business School, Texas A&M
University, College Station, Texas

Instances of the single machine scheduling problem arise often in business and in everyday life. A person faced with several tasks, each of which must be completed by its *due date* (e.g., a student with several assignments), should schedule his/her time so that each is completed on time or with the least possible lateness for each. In scheduling theory, this objective is called *minimizing maximum lateness*. If his/her instructors do not accept assignments late, then the due dates are called *deadlines* and his/her objective changes to *minimizing the weighted number of tardy jobs*, where each task has a *weight* that represents its value, in this case its contribution to the final grade. Companies typically have multiple projects to deliver to customers with contractually stated due dates and penalties assessed for each time unit (e.g., day) by which the job is late. The scheduler of such a company seeks to *minimize total weighted tardiness*. Each project's weight may signify its daily penalty or be a subjective measure of the value of the customer. A supplier providing components for a just-in-time manufacturer (described in ***Just-in-Time/Lean Production Systems***) must minimize both earliness and tardiness of his deliveries.

The single machine scheduling problem is foundational to the study of production scheduling in general because results for a single machine lead to insights into all other scheduling environments. Many exact and heuristic solutions to problems with parallel machines or multiple processing stages (e.g., job shops, flow shops, open shops) are derived by decomposing the system into separate single machines. Furthermore, because it is a special case of the multimachine models (see

the article titled ***Job Shop Scheduling***, and the section titled "Supply Chain Scheduling" in this encyclopedia), if scheduling a single-machine system is shown to be NP-hard [1] for a given objective, then the general scheduling problem for that objective is NP-hard. NP-hard problems are described in depth in the section titled "Network Flows," in this encyclopedia. For this article's purposes, it suffices to know that, given an NP-hard problem, it is highly unlikely that an efficient algorithm—stated precisely, one whose running time is upper bounded by a polynomial in the size of the input for the algorithm—can be developed that will solve a general instance of that problem.

This article summarizes results in the single-machine environment that provide an introduction to the field. These form a basis for deeper study of the topic. The first sections consider the regular performance measurements: the sections titled "Total Weighted Completion Time," "Maximum Lateness," "Maximum of Nondecreasing Cost Functions with Precedence Constraints," "Weighted Number of Tardy Jobs," and "Total Weighted Tardiness." In this context, *regular* means that all jobs are available when processing begins (often called *time zero*) and that the objective function is nondecreasing in the finishing times of the jobs. For such problems, we need to consider schedules without preemption and without idle time [2]. A *preemption* is the interruption of a job's processing to run other jobs on the machine, followed by returning the interrupted job to the machine for its remaining processing time; the preempted job's previous processing is not lost. Excluding preemption and idle time implies that a solution consists simply of a *sequence* of jobs, since each job begins without delay after its immediate predecessor concludes. Later sections describe problems in which both earliness and tardiness are minimized (see the section titled "Earliness and Tardiness Problems") and those in which some jobs are not available when processing

begins (nonzero release dates, defined below) and that allow preemptions (see the section titled “Release Dates and Preemptions.”)

The standard Makespan (completion time of last job) objective is generally not considered in this environment because its value is simply the sum of all processing times, independent of the order in which jobs are performed. One exception is the Makespan with sequence-dependent setup times problem, which can be solved by the Gilmore–Gomory [3] algorithm for the traveling salesman problem (see **Combinatorial Traveling Salesman Problem Algorithms**).

Notation used herein follows that traditionally used in the scheduling literature [4]. The parameters describe characteristics of the jobs to be processed:

- n : number of jobs to be scheduled on the machine
- p_j : processing time of job j
- w_j : weight (value) of job j
- d_j : due date of job j
- r_j : release date of job j . This is the earliest date at which work can begin on job j . By default, $r_j = 0, \forall j$. How nonzero values for r_j may complicate a problem is demonstrated in the section titled “Maximum Lateness.”

The term *date* is used generically in the scheduling literature. It may indicate any point in time, be it a day, an hour, a minute, and so on.

The problems’ variables are performance measurement criteria that are used to compute the objective values of the schedules:

- C_j : completion time of job j
- L_j : lateness of job j : $L_j = C_j - d_j$
- T_j : tardiness of job j : $T_j = \max\{0, C_j - d_j\}$
- U_j : indicator variable for tardiness of job j :
 $U_j = 1$, if $C_j > d_j$; $U_j = 0$, otherwise

We shall use the traditional scheduling classification scheme of Graham *et al.* [5] to describe each problem in the form $\alpha|\beta|\gamma$. The first field indicates the machine environment; hence, $\alpha = 1$ throughout this article. The second field describes processing constraints or

special characteristics. For example, $\beta = r_j$ indicates that the jobs have nonzero release dates, $\beta = s_{jk}$ denotes sequence-dependent setup times, $\beta = prmp$ implies job preemption is allowed, and $\beta = prec$ means precedence constraints apply to some of the jobs. Note that this field may be empty or may contain multiple descriptors. The γ field contains the objective to be minimized. Examples include $\sum w_j C_j$, $L_{\max}$, $\sum w_j U_j$, and $\sum w_j T_j$.

TOTAL WEIGHTED COMPLETION TIME

The total completion time objective provides a measure of work-in-process inventory (see the section titled “Inventory Management and Control” in this encyclopedia). The weights are used to assign different values to the jobs; a weight may represent the actual revenue derived from the job, the holding cost of the job’s inventory, or the importance of its customer. In the scheduling classification scheme [5], this problem is represented by $1||\sum w_j C_j$. The sequence that minimizes this objective is the *weighted shortest processing time (WSPT)* rule [6], which schedules jobs in nondecreasing order of p_j/w_j . Because the method used to prove this result—adjacent pairwise interchange—is commonly used in single machine scheduling research, we include the proof of this result.

Theorem 1. *The WSPT rule is optimal for problem $1||\sum w_j C_j$.*

Proof. Given a set of n jobs, suppose there is some optimal sequence S that is not in WSPT order. There must be two consecutive jobs i then k such that $p_i/w_i > p_k/w_k$. Define T to be the start time of job i and C_j to be the completion time of each job $j = 1, \dots, n$, for sequence S .

Let sequence S' be identical to S except that i and k are reversed. Let C'_j be the completion time of each job $j = 1, \dots, n$, for sequence S' . Obviously, job k starts at time T in sequence S' . Therefore, since every job except i and k complete at the same time in each sequence, the difference in the total weighted completion times for the two

sequences is

$$\begin{aligned}
& \sum w_j C_j - \sum w_j C'_j \\
&= w_i C_i + w_k C_k - (w_i C'_i + w_k C'_k) \\
&= 2T + w_i p_i + w_k (p_i + p_k) \\
&\quad - (2T + w_k p_k + w_i (p_i + p_k)) \\
&= w_k p_i - w_i p_k > 0,
\end{aligned}$$

by the assumption that $p_i/w_i > p_k/w_k$. Hence, sequence S cannot be optimal.

The total completion time problem with release dates ($1|r_j|\sum C_j$) is NP-hard in the strong sense [7]. However, with preemption, the problem ($1|r_j,prmp|\sum C_j$) is solvable by the shortest remaining processing time (*SRPT*) rule [8]. Though the *SRPT* result is generally not feasible for the nonpreemptive problem, it has been used as an effective lower bound for branch-and-bound approaches to this problem [9,10].

It follows from the preceding paragraph that the total weighted completion time problem with release dates ($1|r_j|\sum w_j C_j$) is NP-hard in the strong sense, too. However, a strong lower bound cannot be found by allowing preemption in this case because the corresponding preemptive problem ($1|r_j,prmp|\sum w_j C_j$) is also NP-hard [11]. Nevertheless, effective branch-and-bound schemes have been developed for this problem [12,13].

MAXIMUM OF NONDECREASING COST FUNCTIONS OF C_j

Many due-date related objectives for single machine problems can be expressed as

$$\begin{aligned}
& \text{Minimize } f_{\max} \\
&= \max \{f_1(C_1), f_2(C_2), \dots, f_n(C_n)\},
\end{aligned}$$

where $f_j(C_j)$ is a nondecreasing cost function, $j = 1, \dots, n$. We first look at a specific case—the section titled “Maximum Lateness”—and then at a problem with a general objective of this form that has precedence constraints (see the section titled “Maximum of Nondecreasing Cost Functions with Precedence Constraints”).

Maximum Lateness

Maximum lateness is a measure of the service level. In fact, it measures the satisfaction of the customer who receives the *worst* service. Unsurprisingly, the maximum lateness is minimized by the *earliest due date (EDD)* rule [14], which sequences jobs in nondecreasing order of d_j .

Theorem 2. *The EDD rule is optimal for problem $1||L_{\max}$.*

To illustrate how minor changes to a problem can significantly affect its solution, note that the maximum lateness problem with jobs released at different times ($1|r_j|L_{\max}$) is NP-hard in the strong sense [7].

There are special cases of problem $1|r_j|L_{\max}$ that have polynomial solutions:

- If all release dates are the same, $r_j = r$ for $j = 1, \dots, n$, then the problem reduces to $1||L_{\max}$, which is solved by the *EDD* rule.
- If all due dates are the same, $d_j = d$ for $j = 1, \dots, n$, then an optimal schedule can be found by scheduling the jobs in nondecreasing order of release dates.
- If all jobs have unit processing time, $p_j = 1$ for $j = 1, \dots, n$, then as each job completes, schedule the available job with the smallest due date [15].

Each of these special cases and Theorem 2 can be proven by using adjacent pairwise interchange.

Maximum of Nondecreasing Cost Functions with Precedence Constraints

A precedence constraint requires that a job or set of jobs be completed before a certain job begins. Such constraints are common in scheduling problems. Examples include construction (plumbing and electrical work must be completed before the walls are finished) and curriculum design (an advanced course requires certain prerequisites). The single machine problem of minimizing the maximum cost function if the jobs have arbitrary precedence constraints is denoted $1|prec|f_{\max}$.

Lawler's algorithm [16] to find an optimal sequence uses backward dynamic programming (see the articles in the section titled "Dynamic Programming" of this encyclopedia). Let J be the set of jobs that have not been scheduled and $J' \subseteq J$ be the set of jobs that are currently eligible to be scheduled,

that is, J' is the set of jobs that have no successors currently in J . By starting at the sequence's completion time $C_{\max} = \sum_{j=1}^n p_j$ and working backward, the algorithm schedules in each iteration a job that will end its processing at time $\sum_{j \in J} p_j$. The job so chosen is $j^* = \operatorname{argmin}_{i \in J'} \{f_i(\sum_{j \in J} p_j)\}$.

Algorithm L1973

Step 1: Let $J = \{1, \dots, n\}$, J' be the set of all jobs with no successors in J , and $T = \sum_{j=1}^n p_j$.

Step 2: Let $j^* = \operatorname{argmin}_{i \in J'} \{f_i(\sum_{j \in J} p_j)\}$.

Step 3: Schedule job j^* to be processed during interval $[T - p_{j^*}, T]$.

Step 4: Let $T = T - p_{j^*}$ and $J = J \setminus \{j^*\}$. Update J' by adding those jobs which may now be scheduled, that is, those for which j^* was the only successor.

Step 5: If $J = \emptyset$, then STOP. Otherwise, go to Step 2.

Theorem 3. *Algorithm L1973 produces an optimal schedule for problem 1|prec| $f_{\max}$.*

later in σ than in σ' , and $f_k(T_k) < f_{k'}(T_k)$. Hence, σ' cannot be optimal.

Proof. Suppose σ' is an optimal sequence in which job k' concludes processing at time T_k , that $f_k(T_k) < f_{k'}(T_k)$, and that job $k \in J'$ during the iteration in which job k' was scheduled. Figure 1 displays the order in which the jobs are processed in sequence σ' ; each block represents the time used for its job. A and B are (possibly empty) collections of jobs.

Now suppose that sequence σ' is modified to create sequence σ by scheduling job k during interval $[T_k - p_k, T_k]$ and shifting backward by p_k time units all those jobs that were between jobs k and k' , including k' ; See Fig. 2.

If σ' observes the precedence constraints, then so does σ . Furthermore, $f_{\max}(\sigma) \leq f_{\max}(\sigma')$: job k is the only job that finishes

Figure 1. Sequence σ' for the proof of Theorem 3.

Figure 2. Sequence σ for proof of Theorem 3.

WEIGHTED NUMBER OF TARDY JOBS

The weighted number of tardy jobs metric is commonly used to evaluate managers as it, too, measures the service level (it is equivalent to the weighted number of on time completions) and is easy to track. Recall that a job's weight represents its value to the company (e.g., penalty paid, importance of customer), so this objective quantifies part of a manager's contribution to revenue. The general weighted number of tardy jobs problem is NP-hard [17]; however, we present a polynomial algorithm that solves the unweighted case and a pseudopolynomial algorithm that solves the general problem.

The algorithm of Moore [18] optimally solves the unweighted problem 1|| $\sum U_j$. It begins with all jobs in *EDD* order; without loss of generality, we assume that *EDD* order is $1, 2, \dots, n$. In iteration j , $j = 1, \dots, n$, job j is appended to the ordered set of on-time jobs G^e . If job j 's calculated completion time is larger than its due date ($C_j > d_j$), then the job in G^e with the largest processing time ($\operatorname{argmax}_{k \in G^e} \{p_k\}$) is moved to the set of tardy jobs G^t . This process is continued until all

Algorithm M1968

Input: ordered job set $G = \{1, 2, \dots, n\}$ in *EDD* order, $p_j, d_j, j = 1, 2, \dots, n$

Output: G^e is the ordered set of early jobs, G^ℓ is the set of late jobs

Step 1: Set $G^e = \{1\}$, $G^\ell = \emptyset$, $j = 1$, and $C_1 = p_1$.

Step 2: If $C_j > d_j$, then

Move job $q = \operatorname{argmax}_{k \in G^e} \{p_k\}$ from set G^e to set G^ℓ

Let $C_r = \sum_{i \in G^e} \{p_i\}$

Step 3: Set $j = j + 1$.

If $j \leq n$ then

Set $G^e = G^e \cup \{j\}$

$C_j = C_r + p_j$

Go to Step 2

Step 4: Output schedule $G^e \cup G^\ell$. STOP.

A pseudopolynomial dynamic programming algorithm solves problem $1||\sum w_j U_j$ [19] via recursion. As above, it progresses through jobs $j = 1, 2, \dots, n$, in *EDD* order. For each job j , the algorithm finds the minimum weighted number of tardy jobs incurred when sequencing jobs $\{1, \dots, j\}$ such that job j is completed no later than time $t = p_j, \dots, P_j$, where $P_j = \sum_{k=1}^j p_k$; this quantity is denoted

$F_j(t)$. $F_j(t)$ is calculated as follows: if job j has been scheduled to complete before time t , then $F_j(t) = F_j(t - 1)$. If the objective is minimized by having job j added to the current schedule so that it completes at time t , then $F_j(t) = F_{j-1}(t - p_j)$. Otherwise, if $F_{j-1}(t) + w_j < F_{j-1}(t - p_j)$, then job j is designated as a tardy job. The optimum is $F_n(P_n)$:

Algorithm LM1969

Input: A set of n jobs arranged in *EDD* order, their processing times p_j , their weights w_j , and their due dates d_j .

Initial conditions: $F_0(t) = 0, t \geq 0$; $F_j(t) = \infty, t < 0, j = 1, \dots, n$.

Recursive relation:

$$F_j(t) = \min \begin{cases} F_j(t - 1) \\ F_{j-1}(t - p_j) \\ F_{j-1}(t) + w_j \end{cases}$$

for $j = 1, \dots, n; t = p_j, \dots, P_j$.

Optimum function value: $F_n(P_n)$.

This algorithm runs in $O(nP_n)$ time.

TOTAL WEIGHTED TARDINESS

The total weighted tardiness objective serves as a valuable complement to the number of tardy jobs objective. Monitoring the total weighted tardiness can ensure that a small

number of tardy jobs is not achieved by having those jobs that are tardy be unacceptably late. The total tardiness problem ($1||\sum T_j$) is NP-hard [20], and the total weighted tardiness problem ($1||\sum w_j T_j$) is NP-hard in the strong sense [21].

The pseudopolynomial algorithm that solves the unweighted total tardiness problem [21] also solves to problem 1|| $\sum w_j T_j$ if there are agreeable weights. A problem is said to have *agreeable weights* if $p_i < p_j$ implies $w_i \geq w_j$.

EARLINESS AND TARDINESS PROBLEMS

There are many circumstances in which schedulers wish to avoid both earliness and tardiness. Obviously tardiness may reduce efficiency and customer goodwill, but earliness can lead to unnecessary expense through the accumulation of inventory. Either type of deviation can disrupt a just-in-time manufacturer [22]. Computer systems may want to minimize the range of retrieval times for records in a file in order to provide uniform response to users' requests [23]. Another example is a chemical manufacturer that produces two rapidly deteriorating chemicals that are combined to form a final product. Earliness or lateness

in production of either of these components could diminish productivity [24]. We now consider two approaches to this problem: one minimizes the average deviation of completion times about a common due date, the other minimizes the maximum penalty incurred by any job either for its early start or tardy completion.

Any sequence that minimizes the average deviation of completion times for a set of jobs with a common due date must be V-shaped [25]. Intuitively, the jobs in such a sequence are arranged so that the processing times decrease, reach a minimum, and then increase. Formally, a sequence $\{j_1, j_2, \dots, j_n\}$ is *V-shaped* if there exists some integer $k \in [1, n]$ such that $p_{j_1} \geq \dots \geq p_{j_k} \leq \dots \leq p_{j_n}$. The following algorithm [26] finds an optimal V-shaped sequence by ordering the jobs in nonincreasing order of their processing times then alternatively assigns them to two subsets: those processed before the due date (B), and those processed after the due date (A).

Algorithm K1981

Input: ordered job set $U = \{1, 2, \dots, n\}$ in *longest processing time first* order, common due date d

Output: A sequence that minimizes the average deviation of completion times

$B = A = \emptyset$

For $j = 1$ to n , Step 2

 Assign job j to the last position in B

 Remove j from U

 If $U \neq \emptyset$ then

 Assign job $j + 1$ to the first position in A

 Remove $j + 1$ from U

 End If

Next j

Schedule B so that its last job completes at time d

Schedule A so that its first job starts at time d

Output schedule $B \cup A$. STOP.

A related problem type minimizes the maximum penalty for either earliness or lateness [24]. Each job j has its own target start time (a_j) and target finish time (b_j); no penalty is imposed if the job's processing occurs within the interval

$[a_j, b_j]$. A common example of such a system would be a project described by a critical path method (CPM) network in which each job is assigned an earliest start date (a_j) and a latest finish date (b_j).

A job's earliness is defined by $E_j = \max\{0, a_j - s_j\}$, where s_j is job j 's starting time. Similarly, job j 's lateness is $L_j = \max\{0, s_j + p_j - b_j\}$. The penalty functions for earliness and lateness, respectively, are $g(E_j)$ and $h(L_j)$; they need not be equal, but each is continuous and non-decreasing, with $g(0) = h(0) = 0$. Thus, the objective to be minimized is $z = \max\{g(\max\{E_j\}), h(\max\{L_j\})\}$.

We assume that $a_i < a_j$ implies that $b_i \leq b_j$, which is common for service providers who guarantee a fixed duration for job completion. It follows that an optimal schedule will order jobs so that $a_1 \leq a_2 \leq \dots \leq a_n$ and $b_1 \leq b_2 \leq \dots \leq b_n$; hence, the main task is to determine each job's starting time.

A maximal lower bound on the sum $E_i + L_j$ over all pairs $i < j$ is used to find the minimum objective value. The easily derived lower bound is

$$E_i + L_j \geq \sum_{k=i}^j p_k - (b_j - a_i).$$

It is demonstrated by Fig. 3.

It can be deduced that there is an optimal schedule whose objective value is $g(E^*)$, where E^* and T^* are nonnegative numbers that satisfy the following simultaneous system:

$$\begin{aligned} E^* + T^* &= \max_{i < j} \left\{ \sum_{k=i}^j p_k - (b_j - a_i) \right\} \\ g(E^*) &= h(T^*) \end{aligned}$$

The first equation guarantees that the lower bound on $E_i + L_j$ is feasible, and the second minimizes the objective for this sum. Once E^* is found, the jobs' starting times can be derived as follows:

Figure 3. Demonstration of lower bound for $E_i + L_i$.

Table 1. Example Data for $L_{\max}$ Problem with Nonzero Release Dates and Preemption

	a	b
p_j	5	8
r_j	0	2
d_j	12	10

1. $s_1 = a_1 - E^*$
2. For $j = 2$ to n : $s_j = \max\{s_{j-1} + p_{j-1}, a_j - E^*\}$.

RELEASE DATES AND PREEMPTIONS

The introduction of nonzero release dates implies that an optimal schedule may have idle time. Allowing job preemptions may reduce this idle time and, therefore, the objective value. This ability provides the scheduler with much flexibility. Consider the simple example of $1|r_j, prmp|L_{\max}$ with two jobs given in Table 1.

The standard *EDD* rule would yield the schedule in Fig. 4 with $L_{\max} = 3$.

The *preemptive earliest due date* rule [27] yields the optimal schedule in Fig. 5 with $L_{\max} = 1$.

Now consider the minimization of the maximum of nondecreasing cost functions of C_j , $j = 1, \dots, n$, in this environment, both with and without precedence constraints. Recall that these functions are denoted $f_j(C_j)$ and that this problem with all release dates equal—in which case there is no advantage to preemption—was solved in the section titled “Maximum of Nondecreasing Cost Functions of C_j .” We first solve the general problem then address the minimization of the weighted number of tardy jobs, which

Figure 4. EDD schedule for data in Table 1.

Figure 5. Preemptive EDD schedule for data in Table 1.

was first discussed in the section titled “Weighted Number of Tardy Jobs.”

The concept of *blocks* of jobs is useful for scheduling problems with release dates and preemptions. We first define notation for the total processing time for all jobs within a block B : $p(B) = \sum_{j \in B} p_j$. A *block* B is a minimal set of jobs processed without idle time from $r(B) = \min_{j \in B} \{r_j\}$ until $t(B) = r(B) + p(B)$, such that each job $j \notin B$ is either completed no later than $r(B)$ or not released before $t(B)$.

Given a set N of jobs with no precedence constraints, their release dates r_j , and their processing times p_j , an optimal schedule for the minimization of the maximum of nondecreasing cost functions $(1|r_j, prmp, |f_{\max})$ can be computed as follows [27]:

1. Order the jobs so they are nondecreasing in r_j .
2. Determine the initial block structure by scheduling them in this order, that is, determine where idle time will be imposed by the release dates.
3. For each block B , define $\ell = \operatorname{argmin}_{j \in B} \{f_j(t(B))\}$. The optimal schedule will have $C_\ell = t(B)$, but job ℓ may start earlier than $t(B) - p_\ell$, that is, it may be preempted.
4. Determine the block structure of $B \setminus \{\ell\}$ as in Step 2. Job ℓ will be processed in the times not occupied by $B \setminus \{\ell\}$, that is, if $B \setminus \{\ell\}$ is composed of intervals (subblocks) $B_1, \dots, B_b$, then job ℓ will be processed during the intervals $[r(B), t(B)] - \cup_{i=1}^b [r(B_i), t(B_i)]$.
5. Repeat this process for each subblock.

This algorithm can easily be modified to allow for precedence constraints. Let $j \rightarrow k$ signify that job j must complete before job k can start. This requirement is enforced by adjusting the release date of any such k so that $r_j + p_j \leq r_k$ whenever $j \rightarrow k$. Furthermore, the job ℓ selected in Step 3 must have no successors within its block B .

The weighted number of tardy jobs problem with release dates and preemptions $(1|r_j, prmp, |\sum w_j U_j)$ is NP-hard, but Lawler [28] developed a pseudopolynomial algorithm for it. This algorithm operates in polynomial time when applied to the unweighted problem $(1|r_j, prmp, |\sum U_j)$. Furthermore, when applied to the weighted problem without release dates, it produces an optimal schedule without preemptions. It also solves the problem with release dates but without preemptions if release dates and due dates are similarly ordered, that is, if

$$r_1 \leq r_2 \leq \dots \leq r_n \iff d_1 \leq d_2 \leq \dots \leq d_n.$$

CONCLUDING REMARKS

There are several additional single machine scheduling problems beyond those discussed here. A scheduler may face two objectives, one primary and one secondary. One approach is to solve for the primary one first by applying the appropriate scheduling rule, then, if possible, to address the second by breaking any ties with the scheduling rule for the second. Emmons [29] considered this problem when the primary objective is a nondecreasing cost function of completion times and the secondary is total completion time. Chen and Bulfin [30] developed algorithms to find the schedule with the fewest number of tardy jobs among all those having minimum maximum tardiness. Others [31,32] have sought the set of Pareto Optimal schedules for multicriteria problems. A schedule is *Pareto Optimal* if decreasing the value of one objective necessarily increases the value of another.

Batch scheduling problems in single machine systems fall into two major groups [2,33]. In one, the jobs belong to different families. Jobs within the same family may

be processed consecutively with no setup required between them, but a setup is required when the machine switches families. Another type of batch system allows for multiple jobs to be processed simultaneously on the machine. The machine may have a batch-size limit. Both types of batch scheduling problems are generally solved by dynamic programming.

SINGLE-DIMENSIONAL SEARCH METHODS

EDWIN K. P. CHONG
Department of Electrical and
Computer Engineering, Colorado
State University, Fort Collins,
Colorado

STANISLAW H. ŻAK
School of Electrical and Computer
Engineering, Purdue University,
West Lafayette, Indiana

OVERVIEW

We are interested here in the problem of minimizing a function $f: \mathbb{R} \rightarrow \mathbb{R}$ (i.e., a single-dimensional problem). We refer to f as the *objective function*. The approach is to use an iterative search algorithm, also called a *line-search method*. Single-dimensional search methods are of interest for the following reasons. First, they are special cases of search methods used in multivariable problems. Second, they are used as part of general multivariable algorithms (as described later in the section titled “Line Search in Multidimensional Optimization”).

In an iterative algorithm, we start with an initial candidate solution $x^{(0)}$ and generate a sequence of iterates $x^{(1)}, x^{(2)}, \dots$. For each iteration $k = 0, 1, 2, \dots$, the next point $x^{(k+1)}$ depends on $x^{(k)}$ and the objective function f . The algorithm may use only f , and perhaps its first derivative f' , and even its second derivative f'' . In this article, we study several algorithms:

- Golden section method (uses only f)
- Fibonacci method (uses only f)
- Bisection method (uses only f')
- Secant method (uses only f')
- Newton's method (uses f' and f'').

The exposition here is based on that in Chong and Żak [1, Chapter 7].

GOLDEN SECTION SEARCH

The search methods we discuss in this section and the next allow us to determine the minimizer of an objective function $f: \mathbb{R} \rightarrow \mathbb{R}$ over a closed interval, say $[a_0, b_0]$. The only property that we assume of the objective function f is that it is *unimodal*, which means that f has only one local minimizer. An example of such a function is depicted in Fig. 1.

The methods we discuss are based on evaluating the objective function at different points in the interval $[a_0, b_0]$. We choose these points in such a way that an approximation to the minimizer of f may be achieved in as few evaluations as possible. Our goal is to narrow the range progressively until the minimizer is “boxed in” with sufficient accuracy.

Consider a unimodal function f of one variable and the interval $[a_0, b_0]$. If we evaluate f at only one intermediate point of the interval, we cannot narrow the range within which we know the minimizer is located. We have to evaluate f at two intermediate points, as illustrated in Fig. 2. We choose the intermediate points in such a way that the reduction in the range is symmetric, in the sense that

$$a_1 - a_0 = b_0 - b_1 = \rho(b_0 - a_0),$$

where

$$\rho < \frac{1}{2}.$$

We then evaluate f at the intermediate points. If $f(a_1) < f(b_1)$, then the minimizer must lie in the range $[a_0, b_1]$. If, on the other hand, $f(a_1) \geq f(b_1)$, then the minimizer is located in the range $[a_1, b_0]$ (Fig. 3).

Starting with the reduced range of uncertainty, we can repeat the process and similarly find two new points, say a_2 and b_2 , using the same value of $\rho < \frac{1}{2}$ as before. However, we would like to minimize the number of objective function evaluations while reducing the width of the uncertainty interval. Suppose, for example, that $f(a_1) < f(b_1)$, as in Fig. 3. Then, we know that $x^* \in [a_0, b_1]$.

Figure 1. Unimodal function.

Figure 2. Evaluating the objective function at two intermediate points.

 Figure 3. The case where $f(a_1) < f(b_1)$; the minimizer $x^* \in [a_0, b_1]$.

Because a_1 is already in the uncertainty interval and $f(a_1)$ is already known, we can make a_1 coincide with b_2 . Thus, only one new evaluation of f at a_2 would be necessary. To find the value of ρ that results in only one new evaluation of f , see Fig. 4. Without loss of generality, imagine that the original range $[a_0, b_0]$ is of unit length. Then, to have only one new evaluation of f it is enough to choose ρ so that

$$\rho(b_1 - a_0) = b_1 - b_2.$$

Because $b_1 - a_0 = 1 - \rho$ and $b_1 - b_2 = 1 - 2\rho$, we have

$$\rho(1 - \rho) = 1 - 2\rho.$$

We write the above quadratic equation as

$$\rho^2 - 3\rho + 1 = 0.$$

 Figure 4. Finding value of ρ resulting in only one new evaluation of f .

The solutions are

$$\rho_1 = \frac{3 + \sqrt{5}}{2}, \quad \rho_2 = \frac{3 - \sqrt{5}}{2}.$$

Because we require that $\rho < \frac{1}{2}$, we take

$$\rho = \frac{3 - \sqrt{5}}{2} \approx 0.382.$$

Observe that

$$1 - \rho = \frac{\sqrt{5} - 1}{2},$$

and

$$\frac{\rho}{1 - \rho} = \frac{3 - \sqrt{5}}{\sqrt{5} - 1} = \frac{\sqrt{5} - 1}{2} = \frac{1 - \rho}{1},$$

that is,

$$\frac{\rho}{1 - \rho} = \frac{1 - \rho}{1}.$$

Thus, dividing a range in the ratio of ρ to $1 - \rho$ has the effect that the ratio of the shorter segment to the longer equals the ratio of the longer to the sum of the two. This rule was referred to by ancient Greek geometers as the *golden section*.

If the golden section rule is used it means that at every stage of the uncertainty range reduction (except the first), the objective function f need only be evaluated at one new point. The uncertainty range is reduced by the ratio $1 - \rho \approx 0.61803$ at every stage. Hence, N steps of reduction using the golden section method reduces the range by the factor

$$(1 - \rho)^N \approx (0.61803)^N.$$

Example 1. Suppose that we wish to use the golden section search method to find the value of x that minimizes

$$f(x) = x^4 - 14x^3 + 60x^2 - 70x$$

in the interval $[0, 2]$ (this function comes from an example in Bunday [2]). We wish to locate this value of x to within a range of 0.3.

After N stages, the range $[0, 2]$ is reduced by $(0.61803)^N$. Hence, we choose N so that

$$(0.61803)^N \leq 0.3/2.$$

It requires four stages of reduction; that is, $N = 4$.

Iteration 1. We evaluate f at two intermediate points a_1 and b_1 . We have

$$a_1 = a_0 + \rho(b_0 - a_0) = 0.7639,$$

$$b_1 = a_0 + (1 - \rho)(b_0 - a_0) = 1.236,$$

where $\rho = (3 - \sqrt{5})/2$. We compute

$$f(a_1) = -24.36,$$

$$f(b_1) = -18.96.$$

Thus, $f(a_1) < f(b_1)$, so the uncertainty interval is reduced to

$$[a_0, b_1] = [0, 1.236].$$

Iteration 2. We choose b_2 to coincide with a_1 , and so f need only be evaluated at one new point,

$$a_2 = a_0 + \rho(b_1 - a_0) = 0.4721.$$

We have

$$f(a_2) = -21.10,$$

$$f(b_2) = f(a_1) = -24.36.$$

Now, $f(b_2) < f(a_2)$, so the uncertainty interval is reduced to

$$[a_2, b_1] = [0.4721, 1.236].$$

Iteration 3. We set $a_3 = b_2$ and compute b_3 :

$$b_3 = a_2 + (1 - \rho)(b_1 - a_2) = 0.9443.$$

We have

$$f(a_3) = f(b_2) = -24.36,$$

$$f(b_3) = -23.59.$$

So $f(b_3) > f(a_3)$. Hence, the uncertainty interval is further reduced to

$$[a_2, b_3] = [0.4721, 0.9443].$$

Iteration 4. We set $b_4 = a_3$ and

$$a_4 = a_2 + \rho(b_3 - a_2) = 0.6525.$$

We have

$$f(a_4) = -23.84,$$

$$f(b_4) = f(a_3) = -24.36.$$

Hence, $f(a_4) > f(b_4)$. Thus, the value of x that minimizes f is located in the interval

$$[a_4, b_3] = [0.6525, 0.9443].$$

Note that $b_3 - a_4 = 0.292 < 0.3$.

FIBONACCI METHOD

Recall that the golden section method uses the same value of ρ throughout. Suppose now that we are allowed to vary the value ρ from stage to stage, so that at the k th stage in the reduction process we use a value ρ_k , at the next stage we use a value ρ_{k+1} , and so on. As in the golden section search, our goal is to select successive values of ρ_k , $0 \leq \rho_k \leq 1/2$, such that only one new function evaluation is required at each stage. To derive the strategy for selecting evaluation points, consider Fig. 5. From this figure we see that it is sufficient to choose ρ_k such that

$$\rho_{k+1}(1 - \rho_k) = 1 - 2\rho_k.$$

After a few manipulations, we obtain

$$\rho_{k+1} = 1 - \frac{\rho_k}{1 - \rho_k}.$$

There are many sequences $\rho_1, \rho_2, \dots$ that satisfy the above law of formation and the condition that $0 \leq \rho_k \leq 1/2$. For example, the sequence $\rho_1 = \rho_2 = \rho_3 = \dots = (3 - \sqrt{5})/2$ satisfies the above conditions and gives rise to the golden section method.

Suppose that we are given a sequence $\rho_1, \rho_2, \dots$ satisfying the conditions above and we use this sequence in our search algorithm. Then, after N iterations of the algorithm, the uncertainty range is reduced by a factor of

$$(1 - \rho_1)(1 - \rho_2) \dots (1 - \rho_N).$$

Depending on the sequence $\rho_1, \rho_2, \dots$ we get a different reduction factor. The natural question is as follows: What sequence

$\rho_1, \rho_2, \dots$ minimizes the above reduction factor? This problem is a constrained optimization problem that can be stated formally as

$$\text{minimize } (1 - \rho_1)(1 - \rho_2) \dots (1 - \rho_N)$$

$$\text{subject to } \rho_{k+1} = 1 - \frac{\rho_k}{1 - \rho_k},$$

$$k = 1, \dots, N - 1$$

$$0 \leq \rho_k \leq \frac{1}{2}, k = 1, \dots, N.$$

Before we give the solution to the optimization problem above, we need to introduce the *Fibonacci sequence* $F_1, F_2, F_3, \dots$. This sequence is defined as follows. First, let $F_{-1} = 0$ and $F_0 = 1$ by convention. Then, for $k \geq 0$,

$$F_{k+1} = F_k + F_{k-1}.$$

Some values of elements in the Fibonacci sequence are as follows:

$$\begin{array}{cccccccc} F_1 & F_2 & F_3 & F_4 & F_5 & F_6 & F_7 & F_8 \\ 1 & 2 & 3 & 5 & 8 & 13 & 21 & 34 \end{array}$$

It turns out that the solution to the above optimization problem is

$$\rho_1 = 1 - \frac{F_N}{F_{N+1}},$$

$$\rho_2 = 1 - \frac{F_{N-1}}{F_N},$$

Figure 5. Selecting evaluation points.

$$\begin{aligned}
& \vdots \\
\rho_k &= 1 - \frac{F_{N-k+1}}{F_{N-k+2}}, \\
& \vdots \\
\rho_N &= 1 - \frac{F_1}{F_2},
\end{aligned}$$

where the F_k are the elements of the Fibonacci sequence. The resulting algorithm is called the *Fibonacci search method*. We present a proof for the optimality of the Fibonacci search method later in this section.

In the Fibonacci search method, the uncertainty range is reduced by the factor

$$\begin{aligned}
& (1 - \rho_1)(1 - \rho_2) \dots (1 - \rho_N) \\
&= \frac{F_N}{F_{N+1}} \frac{F_{N-1}}{F_N} \dots \frac{F_1}{F_2} = \frac{F_1}{F_{N+1}} = \frac{1}{F_{N+1}}.
\end{aligned}$$

Because the Fibonacci method uses the optimal values of $\rho_1, \rho_2, \dots$ the above reduction factor is less than that of the golden section method. In other words, the Fibonacci method is better than the golden section method in that it gives a smaller final uncertainty range.

We point out that there is an anomaly in the final iteration of the Fibonacci search method, because

$$\rho_N = 1 - \frac{F_1}{F_2} = \frac{1}{2}.$$

Recall that we need two intermediate points at each stage, one that comes from a previous iteration and another that is a new evaluation point. However, with $\rho_N = 1/2$, the two intermediate points coincide in the middle of the uncertainty interval, and, therefore, we cannot further reduce the uncertainty range. To get around this problem, we perform the new evaluation for the last iteration using $\rho_N = 1/2 - \epsilon$, where ϵ is a small number. In other words, the new evaluation point is just to the left or right of the midpoint of the uncertainty interval. This modification to the Fibonacci method is, of course, of no significant practical consequence.

As a result of the modification above, the reduction in the uncertainty range at the last

iteration may be either

$$1 - \rho_N = \frac{1}{2}$$

or

$$1 - (\rho_N - \epsilon) = \frac{1}{2} + \epsilon = \frac{1 + 2\epsilon}{2},$$

depending on which of the two points has the smaller objective function value. Therefore, in the worst case, the reduction factor in the uncertainty range for the Fibonacci method is

$$\frac{1 + 2\epsilon}{F_{N+1}}.$$

Example 2. Consider the function

$$f(x) = x^4 - 14x^3 + 60x^2 - 70x.$$

Suppose that we wish to use the Fibonacci search method to find the value of x that minimizes f over the range $[0, 2]$, and locate this value of x to within the range 0.3.

After N steps the range is reduced by $(1 + 2\epsilon)/F_{N+1}$ in the worst case. We need to choose N such that

$$\frac{1 + 2\epsilon}{F_{N+1}} \leq \frac{\text{final range}}{\text{initial range}} = \frac{0.3}{2} = 0.15.$$

Thus, we need

$$F_{N+1} \geq \frac{1 + 2\epsilon}{0.15}.$$

If we choose $\epsilon \leq 0.1$, then $N = 4$ is sufficient.

Iteration 1. We start with

$$1 - \rho_1 = \frac{F_4}{F_5} = \frac{5}{8}.$$

We then compute

$$a_1 = a_0 + \rho_1(b_0 - a_0) = \frac{3}{4},$$

$$b_1 = a_0 + (1 - \rho_1)(b_0 - a_0) = \frac{5}{4},$$

$$f(a_1) = -24.34,$$

$$f(b_1) = -18.65,$$

$$f(a_1) < f(b_1).$$

The range is reduced to

$$[a_0, b_1] = \left[0, \frac{5}{4}\right].$$

Iteration 2. We have

$$\begin{aligned} 1 - \rho_2 &= \frac{F_3}{F_4} = \frac{3}{5}, \\ a_2 &= a_0 + \rho_2(b_1 - a_0) = \frac{1}{2}, \\ b_2 &= a_1 = \frac{3}{4}, \\ f(a_2) &= -21.69, \\ f(b_2) &= f(a_1) = -24.34, \\ f(a_2) &> f(b_2), \end{aligned}$$

so the range is reduced to

$$[a_2, b_1] = \left[\frac{1}{2}, \frac{5}{4}\right].$$

Iteration 3. We compute

$$\begin{aligned} 1 - \rho_3 &= \frac{F_2}{F_3} = \frac{2}{3}, \\ a_3 &= b_2 = \frac{3}{4}, \\ b_3 &= a_2 + (1 - \rho_3)(b_1 - a_2) = 1, \\ f(a_3) &= f(b_2) = -24.34, \\ f(b_3) &= -23, \\ f(a_3) &< f(b_3). \end{aligned}$$

The range is reduced to

$$[a_2, b_3] = \left[\frac{1}{2}, 1\right].$$

Iteration 4. We choose $\epsilon = 0.05$. We have

$$\begin{aligned} 1 - \rho_4 &= \frac{F_1}{F_2} = \frac{1}{2}, \\ a_4 &= a_2 + (\rho_4 - \epsilon)(b_3 - a_2) = 0.725, \\ b_4 &= a_3 = \frac{3}{4}, \\ f(a_4) &= -24.27, \\ f(b_4) &= f(a_3) = -24.34, \\ f(a_4) &> f(b_4). \end{aligned}$$

The range is reduced to

$$[a_4, b_3] = [0.725, 1].$$

Note that $b_3 - a_4 = 0.275 < 0.3$.

We now turn to a proof of the optimality of the Fibonacci search method. Skipping the rest of this section does not affect the continuity of the presentation.

To begin, recall that we wish to prove that the values of $\rho_1, \rho_2, \dots, \rho_N$ used in the Fibonacci method, where $\rho_k = 1 - F_{N-k+1}/F_{N-k+2}$, solve the optimization problem

$$\begin{aligned} &\text{minimize} \quad (1 - \rho_1)(1 - \rho_2) \dots (1 - \rho_N) \\ &\text{subject to} \quad \rho_{k+1} = 1 - \frac{\rho_k}{1 - \rho_k}, \\ &\quad \quad \quad k = 1, \dots, N-1 \\ &\quad \quad \quad 0 \leq \rho_k \leq \frac{1}{2}, \quad k = 1, \dots, N. \end{aligned}$$

It is easy to check that the above values of $\rho_1, \rho_2, \dots$ for the Fibonacci search method satisfy the feasibility conditions in the optimization problem above. Recall that the Fibonacci method has an overall reduction factor of $(1 - \rho_1) \dots (1 - \rho_N) = 1/F_{N+1}$. To prove that the Fibonacci search method is optimal, we show that for any feasible values of $\rho_1, \dots, \rho_N$, we have $(1 - \rho_1) \dots (1 - \rho_N) \geq 1/F_{N+1}$.

It is more convenient to work with $r_k = 1 - \rho_k$ rather than ρ_k . The optimization problem stated in terms of r_k is

$$\begin{aligned} &\text{minimize} \quad r_1 \dots r_N \\ &\text{subject to} \quad r_{k+1} = \frac{1}{r_k} - 1, \quad k = 1, \dots, N-1 \\ &\quad \quad \quad \frac{1}{2} \leq r_k \leq 1, \quad k = 1, \dots, N. \end{aligned}$$

Note that if $r_1, r_2, \dots$ satisfy $r_{k+1} = \frac{1}{r_k} - 1$, then $r_k \geq 1/2$ if and only if $r_{k+1} \leq 1$. Also, $r_k \geq 1/2$ if and only if $r_{k-1} \leq 2/3 \leq 1$. Therefore, in the constraints above, we may remove the constraint $r_k \leq 1$, because it is implied implicitly by $r_k \geq 1/2$ and the other constraints.

Therefore, the constraints above reduce to

$$r_{k+1} = \frac{1}{r_k} - 1, \quad k = 1, \dots, N-1,$$

$$r_k \geq \frac{1}{2}, \quad k = 1, \dots, N.$$

To proceed further, we need the following technical lemmas. In the statements of the lemmas, we assume that $r_1, r_2, \dots$ is a sequence that satisfies

$$r_{k+1} = \frac{1}{r_k} - 1, \quad r_k \geq \frac{1}{2}, \quad k = 1, 2, \dots$$

Lemma 1. For $k \geq 2$,

$$r_k = -\frac{F_{k-2} - F_{k-1}r_1}{F_{k-3} - F_{k-2}r_1}.$$

Proof. We proceed by induction. For $k = 2$, we have

$$r_2 = \frac{1}{r_1} - 1 = \frac{1 - r_1}{r_1} = -\frac{F_0 - F_1r_1}{F_{-1} - F_0r_1},$$

and hence the lemma holds for $k = 2$. Suppose now that the lemma holds for $k \geq 2$. We show that it also holds for $k + 1$. We have

$$\begin{aligned} r_{k+1} &= \frac{1}{r_k} - 1 \\ &= \frac{-F_{k-3} + F_{k-2}r_1}{F_{k-2} - F_{k-1}r_1} - \frac{F_{k-2} - F_{k-1}r_1}{F_{k-2} - F_{k-1}r_1} \\ &= -\frac{F_{k-2} + F_{k-3} - (F_{k-1} + F_{k-2})r_1}{F_{k-2} - F_{k-1}r_1} \\ &= -\frac{F_{k-1} - F_kr_1}{F_{k-2} - F_{k-1}r_1}, \end{aligned}$$

where we used the formation law for the Fibonacci sequence.

Lemma 2. For $k \geq 2$,

$$(-1)^k(F_{k-2} - F_{k-1}r_1) > 0.$$

Proof. We proceed by induction. For $k = 2$, we have

$$(-1)^2(F_0 - F_1r_1) = 1 - r_1.$$

But $r_1 = 1/(1 + r_2) \leq 2/3$, and hence $1 - r_1 > 0$. Therefore, the result holds for $k = 2$. Suppose now that the lemma holds for $k \geq 2$. We show that it also holds for $k + 1$. We have

$$\begin{aligned} &(-1)^{k+1}(F_{k-1} - F_kr_1) \\ &= (-1)^{k+1}r_{k+1} \frac{1}{r_{k+1}}(F_{k-1} - F_kr_1). \end{aligned}$$

By Lemma 1,

$$r_{k+1} = -\frac{F_{k-1} - F_kr_1}{F_{k-2} - F_{k-1}r_1}.$$

Substituting for $1/r_{k+1}$, we obtain

$$\begin{aligned} &(-1)^{k+1}(F_{k-1} - F_kr_1) \\ &= r_{k+1}(-1)^k(F_{k-2} - F_{k-1}r_1) > 0, \end{aligned}$$

which completes the proof.

Lemma 3. For $k \geq 2$,

$$(-1)^{k+1}r_1 \geq (-1)^{k+1} \frac{F_k}{F_{k+1}}.$$

Proof. Because $r_{k+1} = \frac{1}{r_k} - 1$ and $r_k \geq \frac{1}{2}$, we have $r_{k+1} \leq 1$. Substituting for r_{k+1} from Lemma 1, we get

$$-\frac{F_{k-1} - F_kr_1}{F_{k-2} - F_{k-1}r_1} \leq 1.$$

Multiplying the numerator and denominator by $(-1)^k$ yields

$$\frac{(-1)^{k+1}(F_{k-1} - F_kr_1)}{(-1)^k(F_{k-2} - F_{k-1}r_1)} \leq 1.$$

By Lemma 2, $(-1)^k(F_{k-2} - F_{k-1}r_1) > 0$, and, therefore, we can multiply both sides of the

inequality above by $(-1)^k(F_{k-2} - F_{k-1}r_1)$ to obtain

$$(-1)^{k+1}(F_{k-1} - F_k r_1) \leq (-1)^k(F_{k-2} - F_{k-1}r_1).$$

Rearranging yields

$$(-1)^{k+1}(F_{k-1} + F_k)r_1 \geq (-1)^{k+1}(F_{k-2} + F_{k-1}).$$

Using the law of formation of the Fibonacci sequence, we get

$$(-1)^{k+1}F_{k+1}r_1 \geq (-1)^{k+1}F_k,$$

which upon dividing by F_{k+1} on both sides gives the desired result.

We are now ready to prove the optimality of the Fibonacci search method and the uniqueness of this optimal solution.

Theorem 1. *Let $r_1, \dots, r_N$, $N \geq 2$, satisfy the constraints*

$$\begin{aligned} r_{k+1} &= \frac{1}{r_k} - 1, \quad k = 1, \dots, N-1, \\ r_k &\geq \frac{1}{2}, \quad k = 1, \dots, N. \end{aligned}$$

Then,

$$r_1 \cdots r_N \geq \frac{1}{F_{N+1}}.$$

Furthermore,

$$r_1 \cdots r_N = \frac{1}{F_{N+1}}$$

if and only if $r_k = F_{N-k+1}/F_{N-k+2}$, $k = 1, \dots, N$. In other words, the values of $r_1, \dots, r_N$ used in the Fibonacci search method form a unique solution to the optimization problem.

Proof. By substituting expressions for $r_1, \dots, r_N$ from Lemma 1 and performing the appropriate cancellations, we obtain

$$\begin{aligned} r_1 \cdots r_N &= (-1)^N(F_{N-2} - F_{N-1}r_1) \\ &= (-1)^N F_{N-2} + F_{N-1}(-1)^{N+1}r_1. \end{aligned}$$

Using Lemma 3 we have

$$\begin{aligned} r_1 \cdots r_N &\geq (-1)^N F_{N-2} + F_{N-1}(-1)^{N+1} \frac{F_N}{F_{N+1}} \\ &= (-1)^N (F_{N-2}F_{N+1} - F_{N-1}F_N) \frac{1}{F_{N+1}}. \end{aligned}$$

It is readily checked that the following identity holds: $(-1)^N(F_{N-2}F_{N+1} - F_{N-1}F_N) = 1$. Hence,

$$r_1 \cdots r_N \geq \frac{1}{F_{N+1}}.$$

From the above we see that

$$r_1 \cdots r_N = \frac{1}{F_{N+1}}$$

if and only if

$$r_1 = \frac{F_N}{F_{N+1}}.$$

This is simply the value of r_1 for the Fibonacci search method. Note that fixing r_1 determines $r_2, \dots, r_N$ uniquely.

For further discussion on the Fibonacci search method and its variants, see Wilde [3].

BISECTION METHOD

Again we consider the problem of finding the minimizer of an objective function $f: \mathbb{R} \rightarrow \mathbb{R}$ over an interval $[a_0, b_0]$. As before, we assume that the objective function f is unimodal. Further, suppose that f is continuously differentiable and that we can use values of the derivative f' as a basis for reducing the uncertainty interval.

The *bisection method* is a simple algorithm for successively reducing the uncertainty interval based on evaluations of the derivative. To begin, let $x^{(0)} = (a_0 + b_0)/2$ be the midpoint of the initial uncertainty interval. Next, evaluate $f'(x^{(0)})$. If $f'(x^{(0)}) > 0$, then we deduce that the minimizer lies to the *left* of $x^{(0)}$. In other words, we reduce the uncertainty interval to $[a_0, x^{(0)}]$. On the other hand, if $f'(x^{(0)}) < 0$, then we deduce that the minimizer lies to the *right* of $x^{(0)}$. In this case, we reduce the uncertainty interval to $[x^{(0)}, b_0]$.

Finally, if $f'(x^{(0)}) = 0$, then we declare $x^{(0)}$ to be the minimizer and terminate our search.

With the new uncertainty interval computed, we repeat the process iteratively. At each iteration k , we compute the midpoint of the uncertainty interval. Call this point $x^{(k)}$. Depending on the sign of $f'(x^{(k)})$ (assuming that it is nonzero), we reduce the uncertainty interval to the left or right of $x^{(k)}$. If at any iteration k we find that $f'(x^{(k)}) = 0$, then we declare $x^{(k)}$ to be the minimizer and terminate our search.

Two salient features distinguish the bisection method from the golden section and Fibonacci methods. First, instead of using values of f , the bisection method uses values of f' . Second, at each iteration, the length of the uncertainty interval is reduced by a factor of $1/2$. Hence, after N steps, the range is reduced by a factor of $(1/2)^N$. This factor is smaller than in the golden section and Fibonacci methods.

Example 3. Recall Example 1 where we wish to find the minimizer of

$$f(x) = x^4 - 14x^3 + 60x^2 - 70x$$

in the interval $[0, 2]$ to within a range of 0.3 . The golden section method requires at least four stages of reduction. If, instead, we use the bisection method, we would choose N so that

$$(0.5)^N \leq 0.3/2.$$

In this case, only three stages of reduction are needed.

NEWTON'S METHOD

Suppose again that we are confronted with the problem of minimizing a function f of a single real variable x . We assume now that at each measurement point $x^{(k)}$ we can determine $f(x^{(k)})$, $f'(x^{(k)})$, and $f''(x^{(k)})$. We can fit a quadratic function through $x^{(k)}$ that matches its first and second derivatives with that of the function f . This quadratic has the form

$$q(x) = f(x^{(k)}) + f'(x^{(k)})(x - x^{(k)}) + \frac{1}{2} f''(x^{(k)})(x - x^{(k)})^2.$$

Note that $q(x^{(k)}) = f(x^{(k)})$, $q'(x^{(k)}) = f'(x^{(k)})$, and $q''(x^{(k)}) = f''(x^{(k)})$. Then, instead of minimizing f , we minimize its approximation q . The first-order necessary condition for a minimizer of q yields

$$0 = q'(x) = f'(x^{(k)}) + f''(x^{(k)})(x - x^{(k)}).$$

Setting $x = x^{(k+1)}$, we obtain

$$x^{(k+1)} = x^{(k)} - \frac{f'(x^{(k)})}{f''(x^{(k)})}.$$

Example 4. Using Newton's method, we will find the minimizer of

$$f(x) = \frac{1}{2}x^2 - \sin x.$$

Suppose that the initial value is $x^{(0)} = 0.5$, and that the required accuracy is $\epsilon = 10^{-5}$, in the sense that we stop when $|x^{(k+1)} - x^{(k)}| < \epsilon$.

We compute

$$f'(x) = x - \cos x, \quad f''(x) = 1 + \sin x.$$

Hence,

$$\begin{aligned} x^{(1)} &= 0.5 - \frac{0.5 - \cos 0.5}{1 + \sin 0.5} \\ &= 0.5 - \frac{-0.3775}{1.479} \\ &= 0.7552. \end{aligned}$$

Proceeding in a similar manner, we obtain

$$\begin{aligned} x^{(2)} &= x^{(1)} - \frac{f'(x^{(1)})}{f''(x^{(1)})} \\ &= x^{(1)} - \frac{0.02710}{1.685} = 0.7391, \\ x^{(3)} &= x^{(2)} - \frac{f'(x^{(2)})}{f''(x^{(2)})} \\ &= x^{(2)} - \frac{9.461 \times 10^{-5}}{1.673} = 0.7390, \\ x^{(4)} &= x^{(3)} - \frac{f'(x^{(3)})}{f''(x^{(3)})} \\ &= x^{(3)} - \frac{1.17 \times 10^{-9}}{1.673} = 0.7390. \end{aligned}$$

Figure 6. Newton's algorithm with $f''(x) > 0$.

Figure 7. Newton's algorithm with $f''(x) < 0$.

Note that $|x^{(4)} - x^{(3)}| < \epsilon = 10^{-5}$. Furthermore, $f'(x^{(4)}) = -8.6 \times 10^{-6} \approx 0$. Observe that $f''(x^{(4)}) = 1.673 > 0$, so we can assume that $x^* \approx x^{(4)}$ is a strict minimizer.

Newton's method works well if $f''(x) > 0$ everywhere (Fig. 6). However, if $f''(x) < 0$ for some x , Newton's method may fail to converge to the minimizer (see Fig. 7).

Newton's method can also be viewed as a way to drive the first derivative of f to zero. Indeed, if we set $g(x) = f'(x)$, then we obtain a formula for iterative solution of the equation $g(x) = 0$:

$$x^{(k+1)} = x^{(k)} - \frac{g(x^{(k)})}{g'(x^{(k)})}.$$

In other words, we can use Newton's method for zero finding.

Example 5. We apply Newton's method to improve a first approximation, $x^{(0)} = 12$, to

the root of the equation

$$g(x) = x^3 - 12.2x^2 + 7.45x + 42 = 0.$$

We have $g'(x) = 3x^2 - 24.4x + 7.45$.

Performing two iterations yields

$$x^{(1)} = 12 - \frac{102.6}{146.65} = 11.33,$$

$$x^{(2)} = 11.33 - \frac{14.73}{116.11} = 11.21.$$

Newton's method for solving equations of the form $g(x) = 0$ is also referred to as *Newton's method of tangents*. This name is easily justified if we look at a geometric interpretation of the method when applied to the solution of the equation $g(x) = 0$ (Fig. 8).

If we draw a tangent to $g(x)$ at the given point $x^{(k)}$, then the tangent line intersects the

Figure 8. Newton's method of tangents.

Figure 9. Example where Newton's method of tangents fails to converge to the root x^* of $g(x) = 0$.

x axis at the point $x^{(k+1)}$, which we expect to be closer to the root x^* of $g(x) = 0$. Note that the slope of $g(x)$ at $x^{(k)}$ is

$$g'(x^{(k)}) = \frac{g(x^{(k)})}{x^{(k)} - x^{(k+1)}}.$$

Hence,

$$x^{(k+1)} = x^{(k)} - \frac{g(x^{(k)})}{g'(x^{(k)})}.$$

Newton's method of tangents may fail if the first approximation to the root is such that the ratio $g(x^{(0)})/g'(x^{(0)})$ is not small enough (Fig. 9). Thus, an initial approximation to the root is very important.

SECANT METHOD

Newton's method for minimizing f uses second derivatives of f :

$$x^{(k+1)} = x^{(k)} - \frac{f'(x^{(k)})}{f''(x^{(k)})}.$$

If the second derivative is not available, we may attempt to approximate it using first derivative information. In particular, we may approximate $f''(x^{(k)})$ above with

$$\frac{f'(x^{(k)}) - f'(x^{(k-1)})}{x^{(k)} - x^{(k-1)}}.$$

Using the foregoing approximation of the second derivative, we obtain the

Figure 10. Secant method for finding the root.

algorithm

$$x^{(k+1)} = x^{(k)} - \frac{x^{(k)} - x^{(k-1)}}{f'(x^{(k)}) - f'(x^{(k-1)})} f'(x^{(k)}),$$

called the *secant method*. Note that the algorithm requires two initial points to start it, which we denote as $x^{(-1)}$ and $x^{(0)}$. The secant algorithm can be represented in the following equivalent form:

$$x^{(k+1)} = \frac{f'(x^{(k)})x^{(k-1)} - f'(x^{(k-1)})x^{(k)}}{f'(x^{(k)}) - f'(x^{(k-1)})}.$$

Observe that, like Newton's method, the secant method does not directly involve values of $f(x^{(k)})$. Instead, it tries to drive the derivative f' to zero. In fact, as we did for Newton's method, we can interpret the secant method as an algorithm for solving equations of the form $g(x) = 0$. Specifically, the secant algorithm for finding a root of the equation $g(x) = 0$ takes the form

$$x^{(k+1)} = x^{(k)} - \frac{x^{(k)} - x^{(k-1)}}{g(x^{(k)}) - g(x^{(k-1)})} g(x^{(k)}),$$

or, equivalently,

$$x^{(k+1)} = \frac{g(x^{(k)})x^{(k-1)} - g(x^{(k-1)})x^{(k)}}{g(x^{(k)}) - g(x^{(k-1)})}.$$

The secant method for finding the root is illustrated in Fig. 10 (compare this with Fig. 8). Unlike Newton's method, which uses the slope of g to determine the next

point, the secant method uses the “secant” between the $(k-1)$ th and k th points to determine the $(k+1)$ th point.

Example 6. We apply the secant method to find the root of the equation

$$g(x) = x^3 - 12.2x^2 + 7.45x + 42 = 0.$$

We perform two iterations, with starting points $x^{(-1)} = 13$ and $x^{(0)} = 12$. We obtain

$$x^{(1)} = 11.40,$$

$$x^{(2)} = 11.25.$$

Example 7. Suppose that the voltage across a resistor in a circuit decays according to the model $V(t) = e^{-Rt}$, where $V(t)$ is the voltage at time t and R is the resistance value.

Given measurements $V_1, \dots, V_n$ of the voltage at times $t_1, \dots, t_n$, respectively, we wish to find the best estimate of R . By the *best estimate* we mean the value of R that minimizes the total squared error between the measured voltages and the voltages predicted by the model.

We derive an algorithm to find the best estimate of R using the secant method. The objective function is

$$f(R) = \sum_{i=1}^n (V_i - e^{-Rt_i})^2.$$

Hence, we have

$$f'(R) = 2 \sum_{i=1}^n (V_i - e^{-Rt_i}) e^{-Rt_i} t_i.$$

The secant algorithm for the problem is

$$\begin{aligned} R_{k+1} &= R_k - \frac{R_k - R_{k-1}}{\frac{\sum_{i=1}^n (V_i - e^{-R_k t_i}) e^{-R_k t_i} t_i}{-(V_i - e^{-R_{k-1} t_i}) e^{-R_{k-1} t_i} t_i}} \\ &\quad \times \sum_{i=1}^n (V_i - e^{-R_k t_i}) e^{-R_k t_i} t_i. \end{aligned}$$

For further reading on the secant method, see Conte and Boor [4]. Newton's method and the secant method are instances of *quadratic fit* methods. In Newton's method, $x^{(k+1)}$ is the stationary point of a quadratic function that fits f' and f'' at $x^{(k)}$. In the secant method, $x^{(k+1)}$ is the stationary point of a quadratic function that fits f' at $x^{(k)}$ and $x^{(k-1)}$. The secant method uses only f' (and not f'') but needs values from *two* previous points. We leave it to the reader to verify that if we set $x^{(k+1)}$ to be the stationary point of a quadratic function that fits f at $x^{(k)}$, $x^{(k-1)}$, and $x^{(k-2)}$, we obtain a quadratic fit method that uses only values of f :

$$\begin{aligned} x^{(k+1)} &= \frac{\sigma_{12}f(x^{(k)}) + \sigma_{20}f(x^{(k-1)}) + \sigma_{01}f(x^{(k-2)})}{2(\delta_{12}f(x^{(k)}) + \delta_{20}f(x^{(k-1)}) + \delta_{01}f(x^{(k-2)}))}, \end{aligned}$$

where $\sigma_{ij} = (x^{(k-i)})^2 - (x^{(k-j)})^2$ and $\delta_{ij} = x^{(k-i)} - x^{(k-j)}$. This method does not use f' or f'' , but needs values of f from *three* previous points. Three points are needed to initialize the iterations.

A similar approach to fitting (or interpolation) based on higher order polynomials is possible. For example, we could set $x^{(k+1)}$ to be a stationary point of a *cubic* function that fits f' at $x^{(k)}$, $x^{(k-1)}$, and $x^{(k-2)}$.

LINE SEARCH IN MULTIDIMENSIONAL OPTIMIZATION

Single-dimensional search methods play an important role in multidimensional optimization problems. In particular, iterative algorithms for solving such optimization problems [1] typically involve a *line search* at every iteration. To be specific, let $f: \mathbb{R}^n \rightarrow \mathbb{R}$ be a function that we wish to minimize. Iterative algorithms for finding a minimizer of f are of the form

$$\mathbf{x}^{(k+1)} = \mathbf{x}^{(k)} + \alpha_k \mathbf{d}^{(k)},$$

where $\mathbf{x}^{(0)}$ is a given initial point and $\alpha_k \geq 0$ is chosen to minimize $\phi_k(\alpha) = f(\mathbf{x}^{(k)} + \alpha \mathbf{d}^{(k)})$. The vector $\mathbf{d}^{(k)}$ is called the *search direction* and α_k is called the *step size*. Figure 11 illustrates a line search within a multidimensional setting. Note that choice of α_k involves a single-dimensional minimization. This choice ensures that under appropriate conditions,

$$f(\mathbf{x}^{(k+1)}) < f(\mathbf{x}^{(k)}).$$

We may, for example, use the secant method to find α_k . In this case we need the derivative of ϕ_k , which is

$$\phi'_k(\alpha) = \mathbf{d}^{(k)\top} \nabla f(\mathbf{x}^{(k)} + \alpha \mathbf{d}^{(k)}).$$

This is obtained using the chain rule. Therefore, for applying the secant method for the line search the gradient ∇f , the initial line-search point $\mathbf{x}^{(k)}$, and the search direction $\mathbf{d}^{(k)}$ are required. Of course, other single-dimensional search methods may be used for line search [5,6].

Line-search algorithms used in practice involve considerations that we have not yet discussed. First, determining the value of α_k that exactly minimizes ϕ_k may be computationally demanding; even worse, the minimizer of ϕ_k may not even exist. Second, practical experience suggests that it is better to allocate more computational time on iterating the multidimensional optimization algorithm rather than performing exact line searches. These considerations led to the development of conditions for terminating

Figure 11. Line search in multidimensional optimization.

line-search algorithms that would result in low-accuracy line searches while still securing a sufficient decrease in the value of the f from one iteration to the next. The basic idea is that we have to ensure that the step size α_k is not too small or too large.

Some commonly used termination conditions are as follows. First, let $\varepsilon \in (0, 1)$, $\gamma > 1$, and $\eta \in (\varepsilon, 1)$ be given constants. The *Armijo condition* ensures that α_k is not too large by requiring that

$$\phi_k(\alpha_k) \leq \phi_k(0) + \varepsilon \alpha_k \phi'_k(0).$$

Further, it ensures that α_k is not too small by requiring that

$$\phi_k(\gamma \alpha_k) \geq \phi_k(0) + \varepsilon \gamma \alpha_k \phi'_k(0).$$

The *Goldstein condition* differs from Armijo in the second inequality:

$$\phi_k(\alpha_k) \geq \phi_k(0) + \eta \alpha_k \phi'_k(0).$$

The first Armijo inequality and the Goldstein condition are often jointly called the *Armijo–Goldstein condition*. The *Wolfe condition* differs from Goldstein in that it involves only ϕ'_k :

$$\phi'_k(\alpha_k) \geq \eta \phi'_k(0).$$

A stronger variation of this is the *strong Wolfe condition*:

$$|\phi'_k(\alpha_k)| \leq \eta |\phi'_k(0)|.$$

A simple practical (inexact) line-search method is the *Armijo backtracking algorithm*, described as follows. We start with some candidate value for the step size α_k . If this candidate value satisfies a prespecified termination condition (usually the first Armijo inequality), then we stop and use it as the step size. Otherwise, we iteratively *decrease* the value by multiplying it by some constant factor $\tau \in (0, 1)$ (typically $\tau = 0.5$) and recheck the termination condition. If $\alpha^{(0)}$ is the initial candidate value, then after m iterations the value obtained is $\alpha_k = \tau^m \alpha^{(0)}$. The algorithm *backtracks* from the initial value until the termination condition holds. In other words, the algorithm produces a value for the step size of the form $\alpha_k = \tau^m \alpha^{(0)}$ with m being the smallest value in $\{0, 1, 2, \dots\}$ for which α_k satisfies the termination condition.

For more information on practical line-search methods, we refer the reader to Fletcher [5, pp. 26–40], Nash and Sofer [7, Section. 10.5], Bertsekas [8, Appendix C], Gill and Murray [9], and Gill *et al.* [10].

SINGLE-SEARCH-BASED HEURISTICS FOR MULTIOBJECTIVE OPTIMIZATION

MATTHIAS EHROGOTT
Department of Engineering
Science, The University of
Auckland, Auckland, New
Zealand

INTRODUCTION

Multiobjective optimization (MO) is the subfield of operations research that deals with the optimization of several conflicting objectives over some set of feasible solutions. An MO problem can be formulated as

$$\min \{(z_1(x), \dots, z_p(x)) : x \in X\}, \quad (1)$$

where $X \subset \mathbb{R}^n$ is a feasible set in decision or variable space and $z : \mathbb{R}^n \rightarrow \mathbb{R}^p$ is a vector valued objective function consisting of the individual objective functions $z_k, k = 1, \dots, p$. The outcome set $Z = z(X) := \{z(x) : x \in X\} \subset \mathbb{R}^p$ is the image of the feasible set in objective or outcome space. Multiobjective optimization requires optimization over vectors, and because of the absence of a canonical total order of vectors, a definition is needed. A feasible solution $x \in X$ is called efficient (or Pareto optimal) if there does not exist $x' \in X$ such that $z_k(x') \leq z_k(x)$ for all $k = 1, \dots, p$ and $z_j(x') < z_j(x)$ for some j . If x is efficient, then $z(x) = (z_1(x), \dots, z_p(x))$ is called nondominated (sometimes also efficient). The set of efficient solutions is denoted by X_E , the set of nondominated outcomes is denoted Z_N . Solving an MO problem means finding the set Z_N (and for each $z \in Z_N$ at least one $x \in X_E$ such that $z = z(x)$).

Single-search-based heuristics are often applied to combinatorial optimization problems (see the section titled “Combinatorial Optimization/Integer Programming” of this

encyclopedia). A multiobjective combinatorial optimization (MOCO) problem is formulated as

$$\min \{Cx : Ax \geq b, x \in \mathbb{Z}^n\}. \quad (2)$$

Here C is a $p \times n$ objective function matrix, where c^k denotes the k th row of C . A is an $m \times n$ matrix of constraint coefficients and $b \in \mathbb{R}^m$. Usually the entries of C, A and b are integers and the feasible set $X = \{x : Ax \geq b, x \in \mathbb{Z}^n\}$ describes a combinatorial structure such as, for example, spanning trees of a graph, paths, and matchings, in which case $X \subset \{0, 1\}^n$ and is a finite set.

A heuristic (see the section titled “Heuristics and Meta-heuristics” of this encyclopedia) for an MO problem is an algorithm that computes a set of solutions $S \subset \mathbb{R}^n$ without necessarily guaranteeing that any element of S is feasible or efficient. An element of S is locally potentially efficient (with respect to S) if there is no other element of S dominating it. The heuristic proceeds in iterations and stops as soon as some criterion is met, at which stage it is assumed that the image of the current set of locally potential efficient solutions $z(S_{PE})$ is a good approximation of the nondominated set Z_N . Most multiobjective heuristics follow one of two ideas. They either repeatedly apply a single search to find some potentially efficient solutions with each run of the single search. At the end of the procedure the solution sets are merged to define the final approximation. These heuristics are the topic of this article. Population-based heuristics work on a set of solutions and try to improve the whole set of solutions in every iteration.

An important issue is the quality of the heuristic, i.e., how well the final solution set approximates Z_N . Two main aspects are the distance between the elements of $z(S_{PE})$ and Z_N and the distribution of the elements of $z(S_{PE})$ along Z_N . There is a substantial amount of literature on this topic and further references can be found in Zitzler *et al.* [1]. It

is in general difficult to compare two different sets of potentially nondominated outcomes.

In the following, single-search heuristic approaches for MO are explained, covering in detail simulated annealing, tabu search, and (Pareto) local search. Following these sections, some ideas underlying hybrid heuristics are briefly mentioned. At the end of the article some conclusions and suggestions for further reading are given.

SIMULATED ANNEALING

Simulated annealing is a local search technique that avoids getting trapped in local optima by accepting nonimproving solutions with some probability that decreases with the number of iterations. Most simulated annealing-based heuristics for MO are closely related to the original idea. However, it is always necessary to adapt the algorithm to deal with the notion of efficient solutions when defining the scheme for decreasing the temperature, the rule for accepting a new solution with some probability depending on the temperature, the mechanism for covering the whole nondominated set, and the (possible) use of information drawn from a set of solutions.

An Example of a Multiobjective Simulated Annealing (MOSA) Algorithm

A typical and popular simulated annealing algorithm is MOSA proposed by Ulungu [2].

Algorithm 1. Multiobjective Simulated Annealing (MOSA).

```

Input:  $\Lambda$  // Set of weights
 $T, \alpha, T_{\text{stop}}, N_{\text{step}}, N_{\text{stop}}$  // SA parameters
 $X_{\text{PE}} \leftarrow \emptyset$ 
for all  $\lambda \in \Lambda$  do
   $T_0 \leftarrow T; N_{\text{count}} \leftarrow 0; n \leftarrow 0$ 
  randomly draw  $x^n \in X; X_{\text{PE}\lambda} \leftarrow \{x^n\}$ 
  repeat
    randomly draw  $x \in \mathcal{N}(x^n)$ 
    if  $\text{isBetter}(x, x^n)$  or  $\text{isAccepted}(x, x^n, n, T_n, \lambda)$  then
       $X_{\text{PE}\lambda} \leftarrow \text{archive}(X_{\text{PE}\lambda}, x); x^{n+1} \leftarrow x; N_{\text{count}} \leftarrow 0$ 
    else
       $x^{n+1} \leftarrow x^n; N_{\text{count}}++$ 
    end if
     $n++$ ;  $\text{updateParameters}(\alpha, n, T_n)$ 
  until  $\text{isFinished}(N_{\text{count}}, T_n)$ 
end for

```

It uses a predefined set of weight vectors Λ to define search directions in outcome space. The algorithm starts with an initial, randomly generated solution x^0 and employs a neighborhood structure $\mathcal{N}(x)$. MOSA selects a neighbor $x \in \mathcal{N}(x^n)$ and compares x with x^n as follows: If $z_k(x) < z_k(x^n)$ for all $k = 1, \dots, p$, then all the objectives have improved and x is accepted. If there exist k and k' such that $z_k(x) < z_k(x^n)$ and $z_{k'}(x) > z_{k'}(x^n)$, then x and x^n are incomparable and both are potentially efficient. If $z_k(x) \geq z_k(x^n)$ with at least one strict inequality, then x is dominated by x^n . In the latter two cases, x is accepted with decreasing probability, depending on the current “temperature” of the cooling schedule (procedure `isAccepted`) based on the values $\sum_{k=1}^p \lambda_k z_k(x)$ and $\sum_{k=1}^p \lambda_k z_k(x^n)$. The probability of accepting a solution is

$$\min \left\{ 1, \exp \left(\sum_{k=1}^p - \frac{\lambda_k (z_k(x) - z_k(x^n))}{T_n} \right) \right\}.$$

When a neighbor is accepted, the set of potentially efficient solutions $X_{\text{PE}\lambda}$ in direction λ is updated. The search stops after a certain number of iterations, or when a predetermined temperature is reached (procedure `isFinished`). At the end, MOSA combines the sets of potentially efficient solutions in a single set X_{PE} by merging the sets $X_{\text{PE}\lambda}$ (procedure `merge`) for all $\lambda \in \Lambda$.

```

 $X_{PE} \leftarrow \text{merge}(X_{PE\lambda})$ 
return  $X_{PE}$  // set of potentially efficient solutions

```

Other Multiobjective Simulated Annealing Algorithms

The Pareto simulated annealing (PSA) method of Czyzak and Jaskiewicz [3,4] combines simulated annealing principles with ideas from genetic algorithms. A set $S \subset X$ of solutions is determined and used as initial solutions. Each solution in this set is improved iteratively following the same simulated annealing principle, using some of the acceptance rules of Serafini [5]. For a given solution $\bar{x} \in S$, the weights are changed in order to increase the probability of moving it away from its closest neighbor in S denoted by $\bar{x}'$.

The method of Parks and Suppaitnarm [6] does not use search directions or an aggregation of the objectives. Each objective is considered separately, applying only the non-domination definition to select potentially efficient solutions. It uses a set of solutions to ensure the exploration of the complete nondominated set. Suppaitnarm *et al.* [6] give recommendations about the tuning of the parameters (acceptance rule, annealing schedule).

Suman [7] proposes an algorithm that starts with an initial randomly selected solution and stops if at any value of the temperature no solution has been added to X_{PE} for a predetermined number of iterations. In the iterations, a new neighbor solution is selected randomly. If it is potentially efficient, it becomes the new solution; otherwise it is accepted with probability $\exp(-\Delta/T)$, where T is the temperature and Δ is the difference in fitness between the new and the current solution (measured as 1 plus the number of solutions dominating it). Diversification is achieved by a restart from a randomly selected element of X_{PE} .

Smith *et al.* [8] also avoid the use of a scalarizing function and evaluate the fitness of a solution in a similar way, but divided by the size of X_{PE} . Moreover, they do not restrict the size of the archive; in fact, they allow dominated solutions to remain in the archive. In contrast, Bandyopadhyay *et al.*

[9] keep the archive to a limited size by using clustering. Their algorithm stops when the temperature drops to a predefined level, with a specified number of iterations at each level. Once again, acceptance of a solution is based on dominance and the number of solutions in the archive dominating new solutions.

TABU SEARCH

The idea of tabu search is also based on local search. Tabu search algorithms try to avoid revisiting local minima by forbidding moves that lead to solutions visited before. By keeping a list of such tabu moves, the search is driven toward areas of the feasible set that have not been explored before. Despite this general idea, moves that lead to exceptionally good solutions are usually accepted and have their tabu status overridden. In multiobjective tabu search algorithms, it is necessary to adapt the tabu criterion to deal with multiple objectives, to use diversification of the search to ensure coverage of the nondominated set, and possibly to exploit information obtained from a set of solutions.

An Example of a Multiobjective Tabu Search Algorithm

The algorithm of Gandibleux *et al.* [10] carries out a series of searches in the objective space using a reference-point-based scalarizing function. These searches are guided by the current approximation of the nondominated set. The algorithm also employs two tabu lists: list $TmemX$ in decision space prevents a return to previously visited solutions and $TmemY$ in objective space is used for updating objective weights between consecutive searches.

In iteration n , the algorithm searches the neighborhood $\mathcal{N}(x^n)$ of the current solution x^n (procedure `exploreNeighborhood`). The successor $\bar{x}$ of x^n is selected from the list of neighbor solutions $\mathcal{L} \subset \mathcal{N}(x^n)$ as the best

according to the scalarizing function

$$s(z(x), y^U, \lambda) = \min_{1 \leq k \leq p} \left\{ \lambda_k (z_k(x) - y_k^U) \right\} + \rho \sum_{k=1}^p \lambda_k (z_k(x) - y_k^U),$$

where $\rho > 0$ and λ_k are nonnegative weights. The number of candidates in list $\mathcal{L}$ is limited to K solutions. The value of this parameter depends on the neighborhood size ($1 \leq K \leq |\mathcal{N}(x^n)|$). The reference point y^U is the locally determined utopian point $y^U = (y_1^U, \dots, y_p^U)$ over $\mathcal{L}$, where $y_k^U < \min\{z_k(x) : x \in \mathcal{L}\}$ (procedure `utopian`). This point dominates the ideal point given by the lowest objective function value of each objective among the solutions in the neighborhood of the current solution.

The tabu list $TmemX$ is used to avoid cycling (procedures `isTabu` and `updateTabuMemoryX`). The selected solution $\bar{x} \in \mathcal{L}$, which minimizes $s(z(x), y^U, \lambda)$ over $\mathcal{L}$ such that the move $x^n \rightarrow \bar{x}$ is not tabu, becomes the new current solution x^{n+1} . The *tabu daemon* overrides the tabu status of a solution $x' \in \mathcal{N}(x^n)$, if $s(z(x'), y^U, \lambda) \leq s(z(\bar{x}), y^U, \lambda) - \Delta$, with Δ being a threshold value (procedure `TabuDaemon`). Each iteration ends with the identification of the potentially efficient solutions $X_{PE\mathcal{L}}$ in $\mathcal{L}$, which represents a local approximation of the nondominated frontier (procedure `archive`).

The tabu searches are adjusted according to a comparison of the local set of potentially efficient solutions $X_{PE\mathcal{L}}$ compared to the global approximation X_{PE} . If $\bar{x} \in X_{PE\mathcal{L}}$ seems to be a promising solution (defined by the number of solutions in X_{PE} that are dominated by $\bar{x}$ being greater than a threshold η), the current search continues for more iterations (procedure `isPromising`). If, however, $X_{PE\mathcal{L}}$ does not contribute any solutions to X_{PE} , the current neighborhood is said to be sterile (routine `isSterile`) and the number of iterations in the current search process is decreased.

The scalarizing function leads to the exploration of the nondominated frontier in the direction given by the weight vector λ . The diversification strategy updates the weights by changing the values of λ_k according to the change in objective function $z_k(x) - z_k(\bar{x})$, distinguishing the case of deterioration, indifference, weak or strong improvement. If the objective k is weakly or strongly improved, the weight λ_k is either slightly or strongly decreased, whereas in the other cases the weight is increased (procedure `setSearchDirection`). To ensure that all the areas of the nondominated frontier are visited, an objective space tabu list $TmemY$ is used. In case of weak or strong improvement, objective k is declared tabu for a predetermined number of iterations. Thus, its weight cannot be increased for the duration of the tabu tenure.

Algorithm 2. Multiobjective Tabu Search MOTS.

Input: TTX, TTY, μ // tabu tenure in decision and objective space, threshold
 Δ, K // tabu daemon parameter and size of candidate list
 $IterInit$ // initial number of iterations for a tabu search
 $stopConditions$ // conditions to stop the search
 $TmemX, TmemY \leftarrow \emptyset$
 $n \leftarrow 1$
select $x^n \in X; X_{PE} \leftarrow \{x^n\}$
repeat
 // Diversification in Z
 $\lambda \leftarrow setSearchDirection(TmemY, X_{PE}); Iter \leftarrow IterInit$
 repeat
 // Local exploration of the nondominated set by tabu search
 $\mathcal{L} \leftarrow exploreNeighborhood(x^n); \bar{z} \leftarrow utopian(\mathcal{L})$
 $\bar{x} \leftarrow \operatorname{argmin}_{x \in \mathcal{L}} \{s(z(x), y^U, \lambda) : \neg isTabu(move(x^n \rightarrow x), TmemX)\}$
 $x^* \leftarrow TabuDaemon(\bar{x}, \mathcal{L}, TmemX)$

```

if  $x^* = \emptyset$  then
   $x^{n++} \leftarrow \bar{x}$ 
else
   $x^{n++} \leftarrow x^*$ 
end if
// Adjustment of the intensification and update of the approximation
 $TmemX \leftarrow \text{updateTabuMemory}(\text{move}(x^{n-1} \rightarrow x^n), TmemX)$ 
 $X_{PE\mathcal{L}} \leftarrow \{x^n\}$ 
for all  $x \in \mathcal{L}$  do
   $X_{PE\mathcal{L}} \leftarrow \text{archive}(X_{PE\mathcal{L}}, x)$ 
end for
if  $\text{isPromising}(x^n, X_{PE})$  then
  increase  $Iter$ 
end if
if  $\text{isSterile}(X_{PE\mathcal{L}}, X_{PE})$  then
  decrease  $Iter$ 
end if
 $X_{PE} \leftarrow \text{merge}(X_{PE}, X_{PE\mathcal{L}})$ 
until  $Iter$  is performed
until  $\text{stopConditions}$  are fulfilled
return  $X_{PE}$ 

```

Other Tabu Search Methods

The method of Hansen [11] starts with a randomly selected set of solutions that are dispersed throughout the objective space in order to allow searches in different areas of the nondominated set. Weights are defined for each solution with the aim of forcing the search into a certain direction of the non-dominated set and away from other current solutions that are potentially efficient. The algorithm then starts a tabu search from each of the initial solutions. The algorithm has been applied to the knapsack problem and the resource constrained project scheduling problem.

The algorithm of Armentano and Arroyo [12] starts with a set of potentially efficient solutions, constructs their neighborhoods, and selects potentially efficient solutions from the union of these neighborhoods. A limited number K of these solutions that are not tabu are selected to be included in the set of locally potentially efficient solutions, and the others are stored as candidate solutions for possible exploration. To aid the selection of solutions, they are grouped into K clusters. The algorithm uses a diversification scheme that penalizes frequently used moves.

Choobineh *et al.* [13] start with p randomly selected solutions and conduct p tabu

searches in parallel, one for each objective function.

Kulturel-Konak *et al.* [14] begin with a randomly selected feasible solution. In each iteration, they first determine an objective function following a multinomial probability distribution. Then the candidate solution is found according to the single objective tabu search principle for the selected objective and the list of potentially efficient solutions is updated. If this does not happen for a specified number of iterations, any element of X_{PE} is selected for a restart.

The algorithm of Jaeggi *et al.* [15], designed for continuous problems, starts from a single solution, but adapts the use of short term memory (tabu list), medium term memory (list of potentially efficient solutions), and long term memory (regions of Z that have been explored) to the multiobjective case.

PARETO LOCAL SEARCH

Simple local search heuristics for single objective optimization start from an initial solution, proceed to investigate the neighborhood of the current solution to find the best solution in the neighborhood, and stop as soon as no further improvement can be made. Naturally such algorithms stop with a local

optimum and no attempt is made to escape from it. In MO it is necessary to define a local optimum as a set of solutions. $S \subset X$ is locally efficient if each $x \in S$ is such that x is locally efficient with respect to neighborhood N , that is, if for each $x \in S$ there is no $x' \in N(x)$ such that $z(x')$ dominates $z(x)$ and such that no element of S is dominated by another one, that is, S is a set of potentially efficient solutions, as discussed by Paquete *et al.* [16].

Very few algorithms based on the local search idea with locally efficient sets have been proposed. We present the generic algorithm given by Paquete *et al.* [16]. The algorithm starts with a single solution, maintains

Algorithm 3. Pareto Local Search PLS.

```

Select initial solution  $x$ 
 $X_T \leftarrow \{x\}; X_V \leftarrow \emptyset$ 
repeat
  Select  $x$  in  $X_T$ ;  $X_V \leftarrow X_V \cup \{x\}$ ;  $W \leftarrow \emptyset$ 
  for all  $x' \in N(x)$  do
    if there is no  $x'' \in W \cup X_V \cup X_T$  with  $z(x'') \leq z(x')$  then
       $W \leftarrow W \cup \{x'\}$ 
    end if
   $X_V \leftarrow \{x' \in X_V : \text{there is no } x'' \in W \text{ dominating } x'\}$ 
   $X_T \leftarrow \text{merge}(V_F \setminus \{x\}, W)$ 
end for
until  $X_T = \emptyset$ 
return  $X_{PE} \leftarrow X_V$ 

```

HYBRID METAHEURISTICS

While originally most single-search-based algorithms were devised along the lines of the single objective versions of the algorithmic paradigms of simulated annealing and tabu search with the main difference being whether a scalarization function was applied or whether the neighborhood search was applied to several starting points using an adaptation of the acceptance principle of new solutions to the efficiency principle, the trend in new algorithms then changed to the development of hybrid heuristics. Hybrid metaheuristics combine ideas from single-search-based heuristics and population-based heuristics. Hybrid metaheuristics can be grouped into several categories.

- Algorithms that include local search within a population-based method. An

archive of potentially efficient solutions, and iteratively investigates all neighbors of all solutions in the archive. X_{PE} is divided into X_V , containing solutions whose neighborhood has been explored, and X_T , solutions whose neighborhood remains to be investigated. In each iteration, the algorithm visits all neighbors of a solution x from X_T . If $x' \in N(x)$ is not dominated by any solution in $N(x) \cup X_V \cup X_T$, then it is added to a set W and will be chosen later unless it becomes dominated by some element of $N(x) \cup X_V \cup X_T$.

example is an algorithm of Jaszkievicz [17], which is a combination of a multiobjective genetic algorithm and local search.

- Algorithms managing coverage of the whole nondominated set using a population of solutions. Some of the algorithms mentioned in the sections titled “Other Multiobjective Simulated Annealing Algorithms” and “Other Tabu Search Methods” actually fall under this category.
- Because population-based methods are particularly well suited for managing a varied set of solutions, they are often strong in covering the whole nondominated set, whereas single-search-based methods can provide a better focus on improving individual solutions. Hybrid methods can exploit the complementary strengths of population-based

and single-search-based algorithms. Examples are the algorithms described by Ben Adbelaziz *et al.* [18], combining a genetic algorithm with tabu search, and López-Ibáñez *et al.* [19], combining an ant colony approach with tabu search.

- Approaches combining heuristics with exact methods and constraint programming have been proposed. In general, a trend is emerging toward custom-made heuristics for specific problems that combine various ingredients from a number of heuristics as well as the exact method. Examples include those of Barichard and Hao [20] and Gandibleux and Fréville [21].

CONCLUSION AND SUGGESTIONS FOR FURTHER READING

In this article, the main approaches for single-search-based heuristics for MO have been explained. These are MOSA, MOTS, and PLS. For each approach one complete algorithm has been presented together with brief explanations of other ideas presented in the literature over time. A brief summary of the trend toward hybrid heuristics has been given.

The related literature is very extensive and a few suggestions for further reading are presented now. Jones *et al.* [22] analyzed the literature until 2002. Ehrgott and Gandibleux [23] present a survey of multi-objective metaheuristics up to 2004. In Ref. 24 the same authors cover hybrid heuristics in depth. All of these survey articles contain many references. Books covering the subject include Gandibleux *et al.* [25] and Talbi [26].

SLOVAK SOCIETY FOR OPERATIONS RESEARCH

ZLATICA IVANICOVA
Department of Operations Research and
Econometrics, Faculty of Economic
Informatics, University of Economics,
Bratislava, Slovak Republic

Slovak Society for Operations Research (Slovenská spoločnosť pre operačný výskum) was established in 1993 after splitting the Czechoslovak Society for Operations Research into the Slovak and Czech Societies. These days, the society has 75 members of which 14 are guests from the Czech Society for Operations Research.

The aims of the Slovak Society for Operations Research are as follows:

1. *To Support the Development of Operations Research as a Scientific Discipline.* For this purpose, the Society organizes meetings, conferences, and seminars; and supports publishing scientific and applied results in operations research. It organizes scientific study trips of its members at institutions, the work of which is oriented to the theoretical development or applications of operations research both in the Slovak republic and abroad.
2. *To Support Educational and Enlightenment Activities Devoted to the Area of Operations Research.* For this purpose, the Society organizes lectures and panel discussions for people working in the management sphere of industry, commerce, and agriculture; in the central management institutions; and education with the aim of informing them about the possibilities of applications of operations research in the spheres of their professional activity. It carries out the advisory activity concerning the possibilities of gaining qualification in operations research in all public and private institutions. The Society

is the custodian of the standardization of operations research terminology in Slovak languages.

3. *To Inform Others about Useful Applications of Operations Research Methods.* For this purpose, the Society provides free-of-charge orientation consultations for private firms and public institutions. The consultations are provided by those members of the Society who have the best professional abilities for the successful solution of the given problem. The Society supports the consultation activity in operations research, which is carried out on a commercial basis, and gives objective information about its level.
4. *To Organize and Coordinate Contacts with Partner Institutions of a Similar Type Abroad.* For this purpose, the Society supports within the framework of its budget, the participation of its members at specialized conferences abroad and organizes the working trips of foreign operations research specialists to the Slovak republic.

The history of individuals who served as presidents of the Slovak Society for Operations Research after splitting from the Czech Society for Operations Research is as follows:

1993–1995	Prof. Ing. Jozef Sojka, CSc
1995–1997	Asst. Prof. Ing. Michal Fendek, CSc
1997–1999	Asst. Prof. Ing. Vladimír Mlynarovič, CSc
1999–2001	Prof. Ing. Zlatica Ivaničová, Ph. D
2001–2004	Prof. Ing. Mgr. Jaroslav Husár, CSc
2004–2007	Asst. Prof. Ing. Ivan Brezina, Ph. D
2007–2010	Prof. Ing. Michal Fendek, Ph. D

Current Representatives of Slovak Society for Operations Research

President: Prof. Ing. Michal Fendek, Ph. D.

Vice-President: Prof. Ing. Zlatica Ivaničová, Ph. D.

Secretary: Ing. Marian Reiff, Ph. D.

Treasurer: Ing. Kvetoslava Surmanová, Ph. D.

ACTIVITIES OF THE SLOVAK SOCIETY FOR OPERATIONS RESEARCH

International Workshop on Quantitative Methods in Science and Practice

This workshop is organized every second year for the members of the Slovak Society for Operations Research and representatives from the Czech Republic (namely, University of Economics, Prague and Technical University in Ostrava). It deals with study programs oriented toward operations research for doctoral, graduate, and undergraduate studies. It is important to note that the basic ideas of the lectures and seminars aimed at operations research were established at the Department of Economic and Mathematical Methods in the year 1961, and later known as the Department of Operations Research and Econometrics, at the University of Economics in Bratislava. Professors of the Slovak Society for Operations Research are, in principle, the supervisors of the lectures and seminars focused on the operations research offered in other universities in Slovakia. Besides the University of Economics in Bratislava, aspects of operations research are also taught at Comenius University in Bratislava, Slovak Agricultural University in Nitra, and University of Zilina, and partly at the technical universities in Bratislava and Košice. Subjects of operations research are modified according to the specific study programs of the above-mentioned universities.

International Conferences on Quantitative Methods in Economics

The Slovak Society for Operations Research organizes the international conferences on “Quantitative Methods in Economics” (multiple criteria decision making), every

second year. Presentations are focused on the methodology and construction of the models and applications of the methods of operations research and econometrics. We would like to stress that each conference is specially devoted to the actual problems of economic policy, on macro and micro levels, solved by models and methods of operations research and econometrics.

The first six international conferences were organized under the Czechoslovak Society for Operations Research. After splitting, the Slovak Society for Operations Research organized the following conferences:

- 14th International Conference—High Tatras, Slovakia 2008
Quantitative Methods in Economics (Multiple criteria decision making XIV)
- 13th International Conference—Bratislava, Slovakia 2006
Quantitative Methods in Economics (Multiple criteria decision making XIII)
- 12th International Conference—Vrútky, Slovakia 2004
Quantitative Methods in Economics (Multiple criteria decision making XII)
- 11th International Conference—Nitra, Slovakia 2002
Quantitative Methods in Economics (Multiple criteria decision making XI)
- 10th International Conference—High Tatras, Slovakia 2000
Quantitative Methods in Economics (Multiple criteria decision making X)
- 9th International Conference—Bratislava, Slovakia 1998
Quantitative Methods in Economics (Multiple criteria decision making IX)
- 8th International Conference—Bratislava, Slovakia 1996
Quantitative Methods in Economics (Multiple criteria decision making VIII)
- 7th International Conference—Bratislava, Slovakia 1994
Quantitative Methods in Economics (Multiple criteria decision making VII).

Proceedings of all international conferences on “Quantitative Methods in Economics” are on the web page <http://www.fhi.sk/en/katedry-fakulty/kove/ssov/papers/>.

SLOVENIAN SOCIETY INFORMATIKA (SSI)–SECTION FOR OPERATIONS RESEARCH (SOR)

LIDIJA ZADNIK STIRN
Biotechnical Faculty,
University of Ljubljana,
Ljubljana, Slovenia

GENERAL DATA

The Slovenian Society INFORMATIKA—Section for Operations Research (SSI-SOR) is a nonprofit professional association of experts and researchers in the field of operations research. The SSI-SOR has its headquarters in Ljubljana, Slovenia. Its postal address is: Vožarski pot 12, 1000 Ljubljana, Slovenia, Phone: +386124153440, Fax: +38612415344, e-mail: sdrobne@fgg.uni-lj.si (Mr. Samo Drobne, Secretary), web page <http://www.drustvo-informatika.si/sekcije/sor>. The President of SSI is Mr. Niko Schlamberger, Slovenian Society INFORMATIKA, Vožarski pot 12, 1000 Ljubljana, Slovenia, Phone: +38641735054; Fax: 38612415344, e-mail: niko.schlamberger@gmail.com. The President of SSI-SOR is Prof. Dr Lidija Zadnik Stirn, University of Ljubljana, Biotechnical Faculty, Chair of Applied Mathematics, Večna pot 83, 1000 Ljubljana, Slovenia, Phone: +386 13205003, Fax: +386 1 2571169, e-mail: lidija.zadnik@bf.uni-lj.si. The secretary of SSI-SOR is Mr. Samo Drobne, M. Sc., University of Ljubljana, Faculty of Civil and Geodetic Engineering, Jamova 2, 1000 Ljubljana, Slovenia, Phone: +386 1 4768649, Fax: +386 1 4250681, e-mail: sdrobne@fgg.uni-lj.si.

The SSI regularly edits the newsletter *Uporabna informatika* (in Slovene language), which is also at the web page [1]: <http://www.drustvo-informatika.si/posta>.

GENERAL FACTS ABOUT SOR

Till the end of 1991, Slovenian researchers and experts from the field of operations

research were active members of the Yugoslav Operations Research Society [2,3].

The Slovenian Section (Chapter) for Operations Research (SOR) at the Slovenian Society INFORMATIKA (SSI) was established in the new state of the Republic of Slovenia in December 1992. The leading persons in the Constitution Committee of SOR were Janez Grad, Viljem Rupnik, Janez Barle, Ludvik Bogataj, Marija Bogataj, Lidija Zadnik Stirn, Samo Drobne, Stane Indihar, Vesna Omladič, and Ivan Meško. There were nearly 40 founding members of the SOR. The first President of SOR was Prof. Ddr. Viljem Rupnik (1992–1997). Mr. Samo Drobne, M.Sc. (1992–) was elected Secretary General of SOR.

The SOR group today consists of 77 members, mostly from universities, (research) institutes, as well as management (firms) in Slovenia. The goal of the group is to pursue, support, and facilitate research, development, application, and education in the operations research area where mathematics, economics, computer science, statistics, environmental economics, and system theory, as well as some other disciplines, come together. Therefore, the interdisciplinary and applied science nature of OR is one of the main concerns of the SOR group. Thus, SOR is a forum for scientists and practitioners from all areas of operations research and allied fields, across the disciplines and programs in resource management, networks, tools, information, and education. In the last few years, its main concern has been to increase its visibility and influence, especially for closer collaboration with educational institutions (universities) and praxis (industry), international collaboration, and publicity.

SOR is managed by an Executive Board elected from the members of the section (chapter). The body has 22 members, of which one is the President of SOR (since 1997, Prof. Dr. Lidija Zadnik Stirn has been the President of SOR), one Vice-President, one Secretary (Mr. Samo Drobne, since 1992), and one Vice-Secretary. SOR has

five honorary members. Operation of SOR is regulated by SSI statute and bylaws. In 1999, the SSI code of professional ethics was proposed and passed at an Extraordinary General Assembly. The operation of SOR is monitored by the SSI Supervisory Board.

Since the inception of SOR, its members have been active in several fields. Among the most important activities is the organization of 10 international symposia on operations research, known as SOR'93, SOR'94, SOR'95, SOR'97, SOR'99, SOR'01, SOR'03, SOR'05, SOR'07, and the jubilee one, the 10th International Symposium on Operational Research SOR'09 [4]. At first, these symposia were organized annually, and later, after an agreement was reached with the Croatian Operational Research Society, they are organized biannually, each year in one country, in Slovenia and Croatia. Operations research symposia in Slovenia consist of plenary sessions, where

several (usually six) prominent scientists present invited papers and about 60 contributed papers in sessions on networks, stochastic and combinatorial optimization, algorithms, multicriteria decision making, scheduling and control, location theory and transport, environment and human resource management, duration models, finance and investment, production and inventory, education and statistics, and OR communications. The presented papers are reviewed by two independent reviewers according to international standards and are published in the form of proceedings. The editors, leading members of SOR, are proud of all 10 SOR Proceedings, especially the last six, which are cited in international publications, such as INSPEC, MathSci, [see the list of SSI-SOR publications below (Fig. 1)].

Further, the members of SOR have written three monographs, two of which,

Figure 1. Cover page of the *Proceedings of the Ninth International Symposium on Operational Research* in Slovenia, SOR'07.

titled *Solutions to Production Problems*, and *Selected Decision Support Models for Production and Public Policy Problems*, are in English [5].

Since 1997, the members of SOR are coeditors of the *Central European Journal of Operations Research* (CEJOR), which is published by Physica-Verlag [6]. In the year 2010, they will be bringing out a special issue of CEJOR devoted to 10 highly professional international symposia organized by SOR.

The members of SOR are also coorganizers of annual meetings in informatics, which take place in Slovenia, and of the biannually organized symposia on Operations Research in Croatia; they actively participate in the INFORMS, EURO, IFORS, KOI, and GOR conferences.

SOR is the 47th member of IFORS, admitted to IFORS at the end of 2007 [7].

Finally, SOR became the 30th member of EURO on July 13, 2008. SOR was admitted to EURO in Sandton during the IFORS conference.

SOR PUBLICATIONS

Proceedings

The SOR published 10 proceedings, which present reviewed articles from the International Operational Research symposia organized by SOR in Slovenia. All the articles in the proceedings are in English [5]. These proceedings are given below:

- Proceedings of the First International Symposium on Operational Research, Slovenia, SOR'93. Edited by V. Rupnik and L. Bogataj, SSI-SOR, Ljubljana 1993, pp. 300.
- Proceedings of the Second International Symposium on Operational Research, Slovenia, SOR'94. Edited by V. Rupnik and M. Bogataj, SSI-SOR, Ljubljana 1994, pp. 280.
- Proceedings of the Third International Symposium on Operational Research, Slovenia, SOR'95. Edited by V. Rupnik and M. Bogataj, SSI-SOR, Ljubljana 1995, pp. 170.

- Proceedings of the Fourth International Symposium on Operational Research, SOR'97. Edited by V. Rupnik, L. Zadnik Stirn, and S. Drobne, SSI-SOR, Ljubljana, 1997, pp. 300.
- Proceedings of the Fifth International Symposium on Operational Research, SOR'99. Edited by V. Rupnik, L. Zadnik Stirn, and S. Drobne, SSI-SOR, Ljubljana, 1999, pp. 370.
- Proceedings of the Sixth International Symposium on Operational Research, SOR'01. Edited by L. Lenart, L. Zadnik Stirn, and S. Drobne, SSI-SOR, Ljubljana, 2001, pp. 403.
- Proceedings of the Seventh International Symposium on Operational Research, SOR'03. Edited by L. Zadnik Stirn, M. Bastiš, and S. Drobne, SSI-SOR, Ljubljana, 2003, pp. 424.
- Proceedings of the Eighth International Symposium on Operational Research, SOR'05. Edited by L. Zadnik Stirn and S. Drobne, SSI-SOR, Ljubljana, 2005, pp. 425.
- Proceedings of the Ninth International Symposium on Operational Research, SOR'07. Edited by L. Zadnik Stirn and S. Drobne, SSI-SOR 2007, pp. 460 (the cover page is presented in Fig. 1).
- Proceedings of the 10th International Symposium on Operational Research, SOR'09. Edited by L. Zadnik Stirn, J. Žerovnik, S. Drobne, and A. Lisec, SSI-SOR 2009, pp. 584.

Monographs

Most of the members of SOR are attached to universities or institutes. Thus, the members of SOR are mostly researchers in the field of operations research or related fields. Some of them, together with their colleagues from abroad, mostly from Croatia, have compiled their work in the form of monographs. Since 1998, SOR has published three monographs:

- V. Rupnik. *Teorija faktorjev integrabilnosti gospodarstva in njihovo praktično*

Figure 2. Cover page of the third book in SDI-SOR series (monograph): *Selected Decision Support Models for Production and Public Policy Problems*.

modeliranje. SSI-SOR, Ljubljana, 1998, pp. 720 (in slovene language).

- *Solutions to Production Problems*. Edited by V. Rupnik, L. Zadnik Stirn, and S. Drobne. SSI-SOR, Ljubljana, 2000, ISBN 961–6165–10–0, pp. 290 (15 chapters in Slovene language, 12 chapters in English).
- *Selected Decision Support Models for Production and Public Policy Problems* (Fig. 2). Edited by L. Zadnik Stirn, L. Ferbar, M. Indihar Štemberger, and S. Drobne. SSI-SOR, Ljubljana 2005 ISBN 961–6165–19–4, pp. 243 (in English).

SOME FACTS ABOUT SSI

The Slovenian Society INFORMATIKA (SSI) was established in 1976 [8]. It is a non-profit association of individuals who work in various areas of information technology, information sciences in business, operations

research, management science, and similar fields in universities, institutes, firms, and administration and who, among other concerns, care to exchange their experience and findings among themselves as well as make it publicly available. SSI members are citizens of Slovenia. In 2006, it was officially recognized as a society that operates in public interest.

SSI is managed by an Executive Board elected from among the members of the Society. The body has 12 members, 4 of whom are the President (for the next four years, Mr. Niko Schlamberger again), President Honorary, and two Vice-Presidents (for next four years it is again Prof. Dr. Lidija Zadnik Stirn and Prof. Dr. Marko Bajec). The operation of the Society is regulated by its statutes and bylaws. In 1999, a Code of Professional Ethics had been proposed and passed at an Extraordinary General Assembly. The operation of SSI is monitored by a Supervisory Board.

The main areas of activities to support the SSI mission are increasing its visibility and influence; closer collaboration with educational institutions, government, and industry; and international activities. The Society has established five chapters headed by Chapter Presidents: Information Systems Research, Operational Research (SOR—established in 1992), Language, History of Computing, and, the most recent, Seniors, which was established in 2007. As of 2000, it is the holder of ECDL (European Computer Driving Licence) in the Republic of Slovenia. International activities are subject to SSI affiliations, which are CEPIS (Council of European professional informatics societies) (1998), IFIP (International federation for information processing) (1998), ECDL Foundation 2000, IT STAR (2001), IFORS (2007), and EURO (2008).

Since 1994, SSI has been awarding recognitions for contributions to computer and information science and for improvement of its work and visibility. So far 44 recognitions have been awarded, of which three in 2008 were for individual achievements, but the recipients may be corporate entities as well. The award ceremony is public and normally takes place during the opening ceremony of the SSI annual conferences.

SSI runs regular and special publications. The regular ones are a quarterly professional journal *Uporabna informatika* (Applied Informatics) in Slovenian language where the Slovenian translation of the Bangemann Report was published, and a scientific periodical *Informatica* in the English language [9]. Special publications are proceedings of conferences and special issues of the journals. Special publications are proceedings, monographs (especially are to be stressed those of SOR, mentioned above), and others.

The main event is the annual open conference Dnevi slovenske informatike (The Days of Slovenian Informatics). It started in 1993 and has since earned the recognition as the most comprehensive event of the year in the field of information sciences in Slovenia. It is a national conference with international participation, and every year noted local and foreign guest speakers are

invited. Other events are international scientific biannual conferences organized by the Chapter of Operational Research (SOR) and other conferences and meetings organized in collaboration with various entities.

The SSI home pages are accessible at www.drustvo-informatika.si.

Publications of SSI

The main publication of SSI is the journal *Uporabna informatika* (Applied Informatics). The journal was started in 1992 and it is the only Slovenian professional informatics journal. Occasionally, there are also papers from foreign authors in the English language. Yearly, there are four regular issues and in the last few years there have been a few special issues each year. Its mission is to inform the professional public and users with up-to-date achievements in informatics in Slovenia and worldwide. A special merit of the journal is its presentation of Slovenian projects and achievement. The journal also informs professionals and the general public on European developments and on important documents, which are the basis of trends in informatics in the European Union and inevitably influence our environment. *Uporabna informatika* was the first to publish the Slovenian translation of the Bangemann Report. It has published the European Ministerial Declaration; the content of a special issue was the Slovenian translation of *The White Book on Information Society in Europe*. A special issue in 2000 titled *The Blue Book—Slovenia as an Information Society* has been a major contribution to the respective national strategy. The journal is edited by the Editorial Board appointed by the Executive Board of the Society from among notable Slovenian professionals—members of the Society. All the articles are reviewed and evaluated regarding their suitability for publication to maintain professional quality and editorial standards. The journal has regular columns: editorial, reports, reviews, solutions, new technologies, and events. The response the editors receive from the readers is an indication that the editorial policy matches the expectations of the readers. The journal

is distributed freely to the members of the Society.

Further, SSI regularly publishes the scientific journal *Informatica*. This journal was started in 1976 as a quarterly international publication for computer sciences and informatics. It is an interdisciplinary journal, the editorial policy of which is oriented toward possibilities of finding and establishing multidisciplinary approaches in newly appearing research and technology niches. The journal has the status of a reference publication in international citation databases such as SCI, SSCI, and TCI. The activity of the Editorial Board indicates an orientation toward increase in the value of the citation indices. Such orientation is strongly supported by the society, as *Informatica* is the only Slovenian scientific journal for informatics that has international recognition. The Editorial Board has set up a worldwide network of editors and reviewers who communicate mainly via electronic mail. In the Board there are about 50 editors and numerous reviewers from about 20 countries all over the world. Occasionally, a special issue is brought out covering a particular topic. Individual numbers are edited by specific domains and columns. The journal covers the domains of computer sciences and informatics, which provide a framework for new fields of research such as artificial intelligence, information theory, robotics, cybernetics and theory of systems, quantum theory of information, criticism of the artificial intelligence, new formal systems, theory of chaos, and others. It also presents reports on strategic projects on leading-edge technologies, on research on information and language, on electronic dictionaries, on archives of knowledge, on microprocessor technology, and similar themes.

For professional Slovene language, that is, the Slovene terminology in informatics and operations research, the publication *Islovar*

is indispensable and of great importance. The Internet interactive IT terminology dictionary (*Islovar*; www.islovar.si) started in 2000 and has been improved continually since. The dictionary is well visited (on average >5000 visits per month) and is recognized as a reference dictionary for government public tenders. There are close to 5000 entries, most of which are edited and reviewed. *Islovar* is open and available at no cost. The plan is to enhance it with the pronunciation.

SOCCER/WORLD FOOTBALL

DAVID R. BRILLINGER
Statistics Department,
University of California,
Berkeley, California

Soccer/world football, also known as *association*, is a sport involving two teams of players kicking and heading a medium-sized ball about on a large rectangular field. Each team has a goal that is quite wide and high and seeks to shoot the ball into the other team's goal. The basic objective is to see which team of the two can score the most goals and thereby win the game. The sport is subject to laws set down by the Fédération Internationale de Football Association (FIFA). Typically, there is a group of teams playing against each other in a league or tournament, with a formal schedule of games. A team's intention then is to win a tournament or championship by winning the final game or scoring the most points, where 3 points are awarded for a win, 1 for a tie, and 0 for a loss.

The sport of soccer has a long and full history possibly going back to 2500 BC [1]. In the present time, the teams each have at most 11 players. One, the goalie, may handle the ball but only within a restricted area in front of the goal. There is a neutral referee whose decisions are final. The grandest tournament, the World Cup, moves amongst different countries and occurs nominally every 4 years. The past world champions are Uruguay, Argentina, Brazil, England, France, Germany, and Italy. The sport has become a multibillion dollar business.

Tactics are basic to the games, with many styles and plating formations available. A team's choice has been based, in part, on studies of match statistics. The pioneer in the field of match performance analysis is Charles Reep [2–4].

DATA COLLECTION AND DESCRIPTIVE ANALYSES

Data collection and analysis have been basic to soccer for many years. The most common statistics are a game's result and the number of goals scored by each team. Outputs of the data analyses include reports, tables, graphs, talks, images, and videos.

Many things go on during a game. A basic question is what is to be recorded for the analysis and how to do so. Charles Reep [2,3] developed solutions starting in the early 1950s. The study of basic events in a game has been called both *match performance analysis* and *match analysis* [2,5–7].

A recent addition to the type of information available for individual games is near-continuous high frequency digital spatial-temporal data. Companies come to a stadium and set up an array of video cameras. By signal processing, they then develop the spatial-temporal coordinates of the changing locations of the players on the field, the ball, the linesmen and the referee. Companies doing this include Match Analysis, Prozone Holdings, and Sport-Universal SA. Di Salvo *et al.* [8] have validated one such system. The basic quantities that may now be tabled directly include counts of tackles, crosses, distances covered, key moments and actions, possessions, passes, interceptions, runs with the ball, incorrect referee decisions, fouls, penalty kicks, challenges, entries into the opponent's area, ball touches, blocks, forward passes, long balls, high intensity running, ball velocity and accuracy, and balls received. Individual player's performances may be evaluated directly. The data can lead to changes in tactics during a game [9,10]. Substantial soccer databases have been available for many years. Websites include www.uefa.com, www.fifa.com [11,12], www.soccerbase.com, www.soccerway.com, and www.soccerpunter.com.

One early investigation of basic data is that of Moroney ([13], pp. 101–103). He studied the numbers of goals scored in 480 games and prepared a histogram of the counts. In another early study, the number of successful passes in passing movements were studied for the English First Division during the years 1957–1958 and 1961–1962 [14]. The results were presented in tabular form. Reep and Benjamin found a stable correspondence between shots on goal and goals scored of about 10 to 1. Distances traveled by individual players during a game are graphed by player position in Ref. 5. Hughes and Franks [15] present scatter and time series plots. One early discovery was the existence of a home advantage. Schedules are often set up so that the two teams meet both, at home and away to deal with this advantage. Jochems [16,17], while addressing the question of whether the Dutch football pools were breaking the gambling laws, found the percentages to be 46.6 for a home win, 31.0 for a visitor win, and 22.4 for a draw/tie. Managers make use of such data in their decision-making, more so every year. Stochastic models are important in this connection.

STOCHASTIC MODELING

Stochastic models are pertinent to soccer statistics, because in part there is much uncertainty in what happens and what may happen. During the preceding 50 years, stochastic models have been constructed to address soccer questions.

Between Game Modeling

Some models may be distinguished as to concerning final goals, win–tie–loss, or points. Specific distributions and models that have been employed include bivariate Poisson, exponential, extreme value, GARCH, generalized linear, logistic, Markov, negative binomial, ordinal, regression, prior, point process, and state space. Many analyses are based on the Poisson distribution whose probability function is given by

$$\text{Prob}\{Y = y\} = \mu^y e^{-\mu} / y! \text{ for } y = 0, 1, 2, \dots$$

Here Y might represent the number of goals a team scores in a future game. In an early work, Moroney [13], using the data mentioned above, compared the number of goals scored by a team in a game to their estimated expected frequency assuming that a Poisson distribution held. On examining the result, he was led to seek to improve it and fit a negative binomial distribution. This is a generalization of the Poisson. This fit was found satisfactory. However, Greenhough *et al.* [18] found that when data from 169 countries were pooled, extreme value distributions were needed.

Reep *et al.* [14,19] work on the number of passes in successful passing movements. They fit the negative binomial and found it was good when 0-length cases were excluded.

Suppose that team i at home is playing against team j visiting. Denote the final score by (X_{ij}, Y_{ij}) with X referring to the home team. Various authors have assumed that X_{ij} and Y_{ij} are independent Poissons with respective means,

$\alpha_i \beta_j, \gamma_i \delta_j$	Ref. 20
$\exp\{\alpha + \eta + \gamma_i + \delta_j\},$ $\exp\{\alpha + \gamma_j + \delta_i\}$	Refs 21 and 22
$\alpha_i \beta_j \eta, \alpha_j \beta_i$	Ref. 23
$\exp\{\alpha + \eta + \gamma_i - \delta_j - \phi$ $X(\varepsilon_i - \varepsilon_j)\}, \exp\{\alpha + \gamma_j - \delta_i$ $+ \phi(\varepsilon_i - \varepsilon_j)\}$	Ref. 24

here η is the home advantage, ϕ a psychological effect, and $\varepsilon_i = \gamma_i + \delta_i$. In their fitting, Dixon and Coles modify the low score model probabilities. The probability that team i wins the game may be estimated having estimated the model parameters.

Maher [20] estimates $\alpha, \beta, \gamma, \delta$ by maximum likelihood and mentions fitting the bivariate Poisson. Karlis and Ntzoufras [25] give details of fitting a bivariate Poisson, studying the data for 24 leagues. They find that the assumption of independence is not rejected in 15 out of the 24 cases. They also consider the negative binomial distribution and the inclusion of interaction terms.

The goal difference $X_{ij} - Y_{ij}$ is also important. It determines whether a game result is

win, tie or loss (W, T , or L) and is used to resolve conflicts when the points are equal. Stefani [26] considers the model

$$X_{ij} - Y_{ij} = \eta + \rho_i - \rho_j + \text{random error}$$

with η the home advantage and ρ_i the rankings. Karlis and Ntzoufras [27] fit the Poisson difference distribution to observed goal differences including a home effect, attacking, and defensive parameters.

Fahrmeir and Tutz [28] employ a logistic latent variable-cutpoint setup to model an ordinal-valued variable. Their model is

$$\begin{aligned} \text{Prob}\{Y_{ij} = r\} &= F(\theta_r + \alpha_i - \alpha_j) \\ &\quad - F(\theta_{r-1} + \alpha_i - \alpha_j) \\ &\text{for } r = W, T, L, \end{aligned}$$

with F the logistic and α_i the ability of team i . In contrast, Brillinger [29–33] employs an extreme value variable-cutpoint approach. It leads to the model

$$\begin{aligned} \text{Prob}\{i \text{ wins at home playing } j\} &= 1 - \exp\{-\exp\{\beta_i + \gamma_j + \theta_2\}\}, \\ \text{Prob}\{i \text{ ties at home against } j\} &= \exp\{-\exp\{\beta_i + \gamma_j + \theta_2\}\} \\ &\quad \times \exp\{-\exp\{\beta_i + \gamma_j + \theta_1\}\}, \\ \text{Prob}\{i \text{ loses at home against } j\} &= \exp\{-\exp\{\beta_i + \gamma_j + \theta_1\}\}, \end{aligned}$$

with $\theta_2 > \theta_1$ cutpoints and the standardizations $\sum \beta_i, \sum \gamma_i = 0$. The parameters β_i and γ_i represent home and away effects of team i . The extreme value distribution employed is longer tailed to the right. The result of the preceding game and the distances between the cities involved were considered as explanatories. The $\beta_i - \gamma_i$ can be interpreted as the advantage of team i when playing at home. These values were also considered in Ref. 34. These authors model the goal differences as

$$X_{ij} - Y_{ij} = \eta + \alpha_i + \beta_j + \text{random error},$$

calling the α_i and β_j “forces.” Least squares estimation is employed. Including past results did not improve things. Goodard [35] fits an ordered probit model, that is, F above relates to the normal, with explanatories.

In a linear regression analysis, Panaretos [36] studies the number of points collected in the course of a double round robin tournament and the effect of the explanatories goals scored, goals conceded, and time of ball possession. The regression model

$$\begin{aligned} \text{points} &= \alpha \\ &+ \beta \log(\text{goals scored}/\text{goals conceded}) \\ &+ \gamma \text{ball possession} + \text{random noise} \end{aligned}$$

is fitted and a proportion of variance explained of 0.971 is found.

Barnett and Hilditch [37] study whether the field being artificial turf affects the game result. They find that the home team’s advantage was increased. The use of artificial turf was abandoned.

Attention now turns to the case where time or round, t , plays an essential role in the modeling. Jochems [16,17] defines, as a measure of strength of team i at home and j visiting, $\lambda_{ij} = W_i - W_j$, with W_i the average points of team i in its preceding games. The prediction of the result for team i is

$$\begin{aligned} i \text{ wins if } \lambda_{ij} &> 0, \\ i \text{ wins if } \lambda_{ij} &= 0 \text{ home advantage,} \\ i \text{ loses if } \lambda_{ij} &< 0. \end{aligned}$$

Jochem’s study had been commissioned by the Netherlands Lottery Commission to see if any skill was involved on the part of tipsters.

The models listed above can be turned into forecasting procedures by simply adding a t to the subscripts of the parameters and estimating them by using the data up to time t . One then uses the schedule of remaining games to develop forecasts. For example, Stefani [26] considers the model

$$X_{ijt} - Y_{ijt} = \eta_{ijt} + \rho_i - \rho_j + \text{random error},$$

with ρ_i a rating based on i ’s past games and $\eta_{ijt} = \pm \eta$ represents a home advantage. The

quantity ρ_i represents team i 's ability. The fit is by conditional least squares.

Dixon and Coles [23] employ independent Poissons and introduce an exponentially decaying time function to damp out the effects of previous rounds. The Poisson means are $\alpha_{i(t)}\beta_{j(t)}\eta$ and $\alpha_{j(t)}\beta_{i(t)}$, respectively. The variable t is time or round number and η stands for home advantage. Estimation is by maximizing the likelihood.

Fahrmeir and Tutz [28] work with a latent variable-motivated ordinal model,

$$\text{Prob}\{R_{ij}^t = r\} = F(\theta_{tr} - \alpha_{ti} - \alpha_{tj}) \\ - F(\theta_{tr-1} - \alpha_{ti} - \alpha_{tj}),$$

with R the result, and $r = 0, 1, 2$ a win-tie-loss indicator. Further F is the logistic, and α_{ti} are random walks in t . The computations involve a Kalman filter and simulation. Rue and Salvesen [24] employ a Bayesian dynamic generalised linear model with independent normals having conditional means given the past

$$\exp\{\alpha + \eta + \gamma_i^t - \delta_j^t - \phi(\varepsilon_i^t - \varepsilon_j^t)\}, \\ \exp\{\alpha + \gamma_j^t - \delta_i^t + \phi(\varepsilon_i^t - \varepsilon_j^t)\},$$

to predict next weekend's results. They employ a directed graph to describe the causal structure of the model as a function of time.

Brillinger [32,33], for each round, t , uses previous round results. He fits a latent variable-based model and then uses simulation to make projections of the final points and standings of the teams using the knowledge of the remaining games in the schedule. Estimates are then available for future rounds.

Harvey and Fernandes [38] study the series of goals scored by England against Scotland in a biyearly match. In a state space approach, they assume a negative binomial model with mean an exponentially decaying function of past values.

Within Game Modeling

Next, consider modeling the progress of a single game. One approach breaks the course

of a game into states corresponding to zones in the field. Pollard and Reep [39] carry out a logistic regression analysis to model the probability of scoring from various positions on the field. In a series of papers [40–42], Markov chains with a finite number of states are employed. Hirotsu and Wright [40] use a four-state model to determine the optimal timing of substitution and tactical decisions. The expected number of points to be gained from a change in tactics is considered an objective function, and dynamic programming is employed. The model includes transition rates of scoring and conceding, and rates of gaining and losing possession. Hirotsu and Wright found evidence for replacing a defender with an attacker when losing.

A common problem is to identify change taking place. Croucher [43] studied the effect of changing the points awarded. The object of this change is to generate more attacking play. Ridder *et al.* [44] study the effect of a red card in game. They infer that the scoring rate does change after the ejection, and has a negative effect on the team with fewer players. Other studies that deal with the effect are given in Refs 45–47. The latter take a point process approach. When team i is playing team j , the times of goals are modeled by Poisson processes with log rates

$$v_{ij}(t) = \lambda_i(t) \exp\{\alpha_j + \beta z_{ij}(t)\} \text{ and} \\ v_{ji}(t) = \lambda_j(t) \exp\{\alpha_i + \beta z_{ji}(t)\},$$

respectively, t being time into the game. The function, $\lambda_i(t)$, is referred to as the *attack intensity* for team i and α_i as the defense parameter. The z_{ij} are the explanatories

$$z_{ij1}(t) = 1 \text{ when rival player off with red} \\ \text{card, 0 otherwise;} \\ z_{ij2}(t) = 1 \text{ if actual score positive;} \\ z_{ij3}(t) = 1 \text{ if actual score negative;}$$

where t is time, β and z_{ij} are the 3 vectors. The parameters are estimated using data from the 2006 World Cup. The fitted model may be employed to generate simulations. Dixon and Robinson [48] also take a point

process approach, employing a birth process, to model the scoring.

The match video data being collected these days may be processed to determine trajectories of players and the ball. Then models can be developed. Xie *et al.* [49] take a video of a game, break it into segments, for example, “play” or “break.” They deal with camera pans and zooms using the green grass ratio and motion intensity. Their analysis uses dynamic programming and spatial-temporal hidden Markov processes. Min *et al.* [50] work on the same problem making use of rule-based reasoning, Bayesian inference, simulation, and expert systems. Palavi *et al.* [51] develops a graph-based multiplayer detection and tracking system. In the simplest case of a notable goal scoring movement in one game, Brillinger [31] develops a potential function approach to obtain a stochastic model.

Berument *et al.* [52] look for evidence of soccer results affecting the Turkish stock market. They do find an effect for one team as well as a day of the week effect.

Garvia [53] asks, “Is soccer dying?” He uses a Markov switching model to look for a break in the series of yearly average goals per game. He finds a drop for England, Italy, and Spain around 1965.

RANKING

Rankings/ratings/seedings are numerical values meant to describe the relative performances of teams in a league. They are used for a variety of specific purposes. One is the preparation of schedules for knock-out tournaments. Another is for the maximization of the probability that the best competitors meet in a tournament’s later stages. If there are N teams the collection of ranking values might be the sequence of integers 1 to N . A famous example is the FIFA/Coca-Cola world ranking [www.fifa.com.worldfootball/ranking/procedure/men.html [54]], where the values derive from a formula involving major games during the previous 4 years, strength of opponent, $W-T-L$ points, and several other items. It orders the teams of all the countries that are

members of the FIFA and is updated steadily as more game results become available.

Jochems [16,17] employed the differences of average game scores and compared this to tipsters’ predictions. Hill [55] uses Kendall’s tau to compare tipster results with the end of season standings and finds association. Stefani [26] suggests the model

$$X_{ij} - Y_{ij} = \eta + \rho_i - \rho_j + \text{random error},$$

with the ρ_i ’s rankings. Stefani [56] surveyed the major world sports rating systems. Bassett [57] suggests improving the estimates by employing a robust estimation method to handle long tails. Forrest and Simmons [58,59] investigate the predictive quality of newspaper tipsters match results. Stefani and Pollard [60] provide a critical survey of ranking procedures. Gelade and Dobson [61] relate the international standing of a country’s team to various social factors including number playing regularly, wealth, and climate. McHale and Davies [62] focus on the FIFA rankings.

There are papers on ratings for other sports; for example, Refs 63–65.

TOURNAMENTS AND SCHEDULING

Scheduling is a basic step involved when games need to be organized amongst the members of a group of teams. Two basic types of tournament design are the round robin and the knock-out. In the round robin, each pair of teams plays against each other the same number of times, equally at home and away. The champion of the group is the team with the most points at the end of all the games. In the knock-out case, there is a seeding order and the first round is based on it. The tournament progresses with two teams playing in pairs setup by the seeding order with the winner going on to the following round. This continues until only one team is left, the champion.

Sometimes there are numerical-valued objective functions that can be employed in developing schedules. Their forms can include distance traveled, total expenses,

numbers of consecutive home or away games, and referees' time. There are often constraints that need to be taken note of in the scheduling. For example, there may be multiple venues, television schedules, desired dates for two teams from the same city. Analytic tools employed in an optimization include integer programming, maximization, knapsack algorithms, simulation and stochastic models.

Kuonen [21,66] employs a logistic regression model and shows how output can be used to estimate probabilities of interest for a knock-out tournament. Unlike a round robin, future opponents for the following rounds are only known probabilistically. Kuonen works with European Cup Winners Cup data. He investigates three methods for calculating seeding coefficients based on the data for the 3 preceding years.

Urban and Russell [67] consider scheduling competitions on multiple venues, venues not associated with any of the participants. Della Croce and Oliveri [68] present an integer linear programming approach for scheduling the Italian League. They had to deal with cable TV and with games between teams in the same city.

Scheduling the Chilean League has also posed special problems. As described in Refs 69 and 70, these were dealt with via using mathematical programming, recognized existing weaknesses, stadiums availability, international requirements, and reducing travel distance.

Objectives may be described probabilistically and then stochastic models are involved. When the goal is to determine a champion, it is natural to ask questions like: what is the probability that the "best" team actually wins the tournament, or how much better is the first team than the second? Appleton [71] provides definitions and reviews many tournament structures. He employs simulations.

Scarf *et al.* [72] provide an extensive review including discussion of: tournament metrics, how the design influences outcome uncertainty, the use of simulation, robustness (to teams dropping out), effects of rule changes, and probability model employed. He defines the parameter

$$P_{qR} = \text{Prob}\{\text{team in top } 100q \text{ pretournament rank percentile progresses advances to round } R + 1\};$$

here R is round achieved and $0 < q < 1$. To understand the P_{qR} values, he graphs them against q .

It is necessary to schedule the referees also. Yavuz *et al.* [73] provide an extensive review. The topics covered include leagues in different countries requiring different objective functions and constraints, tension between referees and clubs caused by past incidents, reducing frequent assignment of the same referee to a team's games. In amateur leagues, there may be several games the same day for the same referee, perhaps at different places even.

GAME THEORY

The expression "game theory" has both a general and a technical meaning. The "technical" comes from the classic Von Neumann–Morgenstern [74] setup. The "general" refers to other things, particularly tactics. Both meanings provide general frameworks with which to study soccer. A difficulty arising in the theories' applications to soccer is that the game is highly dynamic. Jones and Trantner's [75] book is unusual in that, it starts by emphasizing the defensive formations. Wilkinson's [76] book is devoted to the topic of tactics.

The formation selected would be controlled by the coach. The 2-3-5 was very common for many years. In it, there are two defensive specialists, five attacking, and three midfielders in between. Newer formations include 3-5-2, 5-4-1, 4-5-1, 4-3-3, and even 4-1-4-1 with an extra row. The formation 4-4-2 is favored by various famous teams. The two attackers can drop back to assist in obtaining the ball or be on the sides up front. When the team has possession of the ball, the two outside midfielders can move forward to increase pressure on the opponent. Wilson [77] provides a review and insightful analysis of many of the formations employed in games dating from 1878 to 2008.

Pollard and Reep [39] seek to quantify the effectiveness of different playing strategies.

They break the action of a game down into discrete events, for example, pass, center, shoot. They define the “yield” as the probability a goal is scored minus the probability one is conceded. This quantity is used to evaluate the expected outcome of a team possession.

The book, *The Science of Soccer*, has a chapter on “game theory” [78]. It discusses how the strength and deployment of the team moderates the apparent random motion and discusses the fact that low scoring benefits the weaker team.

One of the momentous occasions in a soccer game is the awarding of a penalty shot. There have been a number of formal studies. Greenless *et al.* [79] study how the penalty takers’ uniform color and prepenalty gaze affect the impressions formed by the goal-keeper. When penalties take place to break a tie, McGarry and Franks [80] identify an optimal order for a team to take the shots in. Their conclusion is to begin by ranking the players 1 (best) to 11 (worst). Then use the order: 5, 4, 3, 2, 1, and if necessary after that 6, 7, 8, 9, 10, and 11. Jordet *et al.* [81] considers the roles of stress, skill, and fatigue for answering why the English are poor at penalties. He analyzed 200 shots from World Cup and European Championship. In an analysis of many penalties, Franks *et al.* [82] learned that in 80% of the cases studied, if the nonkicking foot points to the left, the ball will be shot to the left. They developed a training program to test this discovery.

Larsen [2] describes the arrival of Reep’s ideas in Norway and the success that teams adopting it enjoyed.

The theory of von Neumann and Morgenstern provides general definitions and leads to random strategies. Haigh [83] provides the following intuitive example. The table shows estimated percentages of successful penalty shots based on 1876 attempts.

Goalie	Kicker		
	Left	Center	Right
Left	60	90	93
Center	100	30	100
Right	94	85	60

These data concern the goalie’s direction of motion and the direction of the Kicker’s shot.

The situation can be considered is a two-person zero-sum game. If the kicker wins by scoring, the goalie loses. If the goalie wins by saving, the kicker loses. Haigh finds that Nash equilibrium theory leads to the goalie’s choosing to move left, center or right with the respective probabilities of 0.44, 0.13, and 0.43. For the kicker, they are 0.37, 0.29, and 0.34, respectively. If either player uses their strategy, 80% of the shots would be scored in the long run. This turns out to be close to the actual percentage.

Other references to applications of the formal theory include Refs 84–86. Hirotsu and Wright [85] consider a zero-sum game focusing on who wins the game, while Hirotsu *et al.* [87] focus on points gained. Here one has a nonzero-sum game. Bennett *et al.* [88] use hypergame analysis, involving the ranking of various forms of hooligans’ actions and authorities’ reactions followed by hooligan’s reactions and so on. They explore the implications of such scenarios.

ECONOMICS AND MANAGEMENT

Reilly and Williams [89] write, “In the 1980s it became apparent that the football (soccer) industry and professionals in the game could no longer rely on the traditional methods of previous decades. Methods of management science were applied to organizing the big soccer clubs and the training of players could be formulated on a systematic basis.” Desbordes [90, Chapter 10] advocates the introduction of modern management tools into soccer. This makes sense if for no other reason than the fact that billions of dollars are now involved in the sport. One does need to remember that at the youth and amateur levels, the amount of money involved is little. Really, all that is needed for a game is a “ball” and a field or a beach. This is one charm of the game.

Management refers to a sport’s structure, owners, sponsors, marketers, financiers, schedulers, and others with some form of control. Management provides the superstructure. The fans expect both their team’s players and its management to be successful

in acquiring players, providing facilities, and hiring the coach. Management assists by supporting the enterprise generally. It provides the infrastructure. Other things that management is responsible for include cash inflows–outflows, advertising, manpower planning and hiring, planning new and keeping up old stadiums, and signing players. The stadium owners provide facilities for security, ticket collection, food, souvenirs, and parking. Management studies the performance of their players and others [10,91].

Sometimes, there is a numerical-valued objective function for the management to work with. Then optimization methods may be employed to good advantage. Other concerns are loss functions, earnings/revenue, prestige/honor, recruitment, salary negotiation, scouting, referees, merchandise, commercialism, productivity, profitability, travel, and television rights.

There is a common wish to improve individual player's and a team's performance. An accompanying question is how to assess performance and efficiency. One paper on the topic for English soccer is Ref. 92. Others are Refs 93 and 94. The latter concerns the Spanish Soccer League. There have been analyses. Audas *et al.* [95] study the impact of managerial change on team performance using the data of English football match results since the 1970s, while Partovi and Corredoir [96] investigate models for prioritizing and designing rule changes.

In a study of competitive balance in the Dutch League, Koning [97] employs the values C_{ij} , corresponding to W, T, L , generated via

$$\begin{aligned} D_{ij} &= \varphi_i - \varphi_j + \varepsilon_{ij} \text{ with the } \varepsilon\text{'s mean 0,} \\ &\quad \text{common variance normals,} \\ C_{ij} &= 1 \text{ if } D_{ij} > c_2 \\ &= 0 \text{ if } D_{ij} = 0 \\ &= -1 \text{ if } D_{ij} < c_1. \end{aligned}$$

It is used to study changes in competitive balance in Holland.

A novel application of programming theory is presented in Ref. 98. It applies an integer program to the generalized knapsack

problem to find a "Dream Team." Player values were established by a public poll with the participants given a budget of 2.5 million dollars each. A knapsack algorithm was then employed to establish the best team at the lowest price.

Calster *et al.* [99] study an unwanted happening in soccer, the scoreless draw. The occurrence is related to indices of a team's offensive performance including total goals and earned points per game.

SOME REMAINING TOPICS

The book, *The Inner Game of Soccer*, provides details of the game from a referee's standpoint [100]. It discusses the laws and the mechanics and talks of the characteristics of the best referees and the ones who can turn benign games into ugly unsportsman-like confrontations.

Reference 78 lays out some of the physics of soccer. For example, the chapter titled "The ball in flight" analyzes the movement of a ball spinning in flight and how players can make it bend. Hall [101] elaborates on that describing the physical forces at work in a double banana shot, which curves in one direction then swerves in another. Such a shot is very difficult for the goalie to handle.

Sports biomechanics concerns physical actions that occur in sport that can be observed and improved, for example, to reduce injuries. The Refs 102 and 103 are on the topic of biomechanics in soccer. Grimpampi *et al.* [104] concern computational biomechanics. Bradley *et al.*'s study [105] is a human biology study. It refers to results on high-intensity running using data collected via an array of television cameras.

There are many articles on employing stochastic models in evaluating bets. Most of the articles referred to above go on to study the efficiency of various gambling strategies.

What is ahead for the game? Wright [106] writes on 50 years of operations research in sport to provide a background. The future is discussed in Ref. 107 and by the sports writer Garner [108] in *World Soccer*. He suggests the following changes: bigger goals, smaller penalty area, a revised offside rule,

fouls denoted contact or technical, red-carded player punished but replacement allowed. Reviewing the literature and practice suggest that one can expect to see much more in the way of the collection and analysis of the spatial-temporal data collected in a game.

SOCIEDAD PERUANA DE INVESTIGACIÓN OPERATIVA Y DE SISTEMAS (SOPIOS)

ROSA DELGADILLO
DAVID MAURICIO
Universidad Nacional
Mayor de San Marcos,
Lima, Peru

Operations research (OR) has been promoted in Peru by Eugen Blum, a Swiss national and professor of the Mathematics Faculty of the Universidad Nacional Mayor de San Marcos (UNMSM) and the other universities. Eugen Blum promoted the creation of an association for OR in 1985, bringing together students, alumni, and teachers of the OR school (the OR school of Mathematics Faculty was created in 1969). He died in 1993.

ANTECEDENTS AND SOCIETY CREATION

In the year 2006, David Mauricio Sanchez, professor of the Systems Engineering, Faculty of the UNMSM in the Latin Iberoamerican Congress on Operational Research (CLAIO), under the organization of the Association Latin Iberoamerican Operations Research (ALIO), proposed that Peru be the headquarters of the XIII Latin American Summer School on Operations Research (XIII ELAVIO). The proposal was based on the following: (i) it was necessary to encourage the development of the OR field in Peru, and researchers and practitioners needed to be motivated and encouraged; (ii) an ELAVIO had never been held in Peru, so this would be an excellent opportunity to gather national professionals in the field and encourage them to research. The proposal was accepted by the Managerial Committee of ALIO, and in February 2008, the first summer school on OR in Peru was organized, which took place in the district of Chosica, a few kilometers from Lima. The XIII ELAVIO was organized by two universities: the

UNMSM and the Universidad Inca Garcilaso de la Vega. In this academic event, students, professionals, and organizers of the school got together and decided to form the Peruvian Society of Operations Research, with the aim of bringing researchers, practitioners, teachers, graduates, and undergraduates of all universities of Peru interested in developing the OR field. That is, it was thought that the Peruvian Society would bring together professionals from different Peruvian universities with different areas of training with emphasis on the development of the OR field; an *ad hoc* committee was established for the creation of the Peruvian Society of Operations Research, which was composed of professionals from different universities.

In October 25, 2008 officially the Peruvian Society for Operations Research and Systems (SOPIOS) was created, in a general assembly, carried out in the Faculty of Systems Engineering of the UNMSM; in this assembly, the first Managerial Committee constituted by a President, a Vice President, a Secretary, the Administrative Financier Director, a Director of Events and Institutional Image, a Director of Research and Development, and the Director of Education and Publications were chosen. The first managerial committee was chaired by Rosa S. Delgadillo Avila.

The founding members of the SOPIOS were 42 university teachers from UNMSM (Faculty of Systems Engineering, Faculty of Mathematics), Universidad Inca Garcilaso de la Vega, Universidad Nacional de Ingeniería, Universidad Católica Santo Toribio de Mogrovejo of Chiclayo, and Universidad Cesar Vallejo of Trujillo.

SOPIOS, from the legal point of view, is a nonprofit civil association registered in the registry zone No. IX in Lima, with item number 12266253 in the Lima Registry Office. The Managerial and Government organs of SOPIOS are the General Assembly and the Managerial Committee, whose mandate is for two years, similar to the fiscal committee. The associates' General Assembly is summoned at least once a year; however, the Directors

have monthly meetings and constant communication with their members through phone and e-mail.

The purposes of the SOPIOS are as follows [1]:

1. congregating professionals, students, and institutions with interests in OR, systems, and related areas;
2. stimulating activities such as teaching, research and development in OR in Peru;
3. Spreading the applicability of OR and related areas in the sectors of production and service, as a factor of competitiveness and productivity for the national development;
4. supporting the educational entities in subjects related to academic formation in operations research and systems;
5. exchanging experiences and information among professionals, academic and managerial level personnel in the country and abroad, so that it permits progress in OR; and
6. contributing to the technological and scientific research in the country, promoting research, and technology transfer activities.

The following activities are considered for SOPIOS purposes:

1. organizing and promoting OR and systems events at the local, regional, national, and international level periodically;
2. editing publications in OR, systems, and related areas;
3. establishing communication channels and relationship with other national and international organizations, which are interested in the application and development of OR;
4. promoting the integration and application of OR in other areas;
5. advising the implementations of solutions to problems of OR, systems, and related areas, and document the successful cases; and
6. programming the acquisition of funds for accomplishing these objectives.

ACHIEVEMENTS

The group of professionals that participates in SOPIOS, was the group that organized the XIII ELAVIO and the first ELAVIO in Peru, which took place in February 2008 at Chosica-Lima (Fig. 1), with a very good international representation [2]. This event had participants from Peru, Brazil, Cuba, Colombia, Chile, Uruguay, Canada, The Netherlands, Philippines, Israel, and Dominican Republic, with a total of 55 participant students. This ELAVIO was organized by the UNMSM and the Universidad Inca Garcilaso de la Vega and was sponsored by ALIO, International Federation of Operational Research Societies (IFORS), and other institutions such as Consejo Nacional de Ciencia, Tecnología e Innovación Tecnológica (CONCYTEC), and Centro Latinoamericano de estudios en Informática (CLEI).

In June 2008, taking advantage of the visit to Peru by Professor Milan Zeleny of Fordham University, New York, and with the purpose of maintaining the society actively, the International conference “Integración de Conocimiento y gestión de auto-producción” was organized in the System Engineering Faculty of the UNMSM (Fig. 2). This conference stirred up the interest of the professionals and students.

SOPIOS, with their objective to diffuse and to stimulate the research in OR in Peru, has considered to organize national congresses every year, similar to its regional partners, the SPBO (Brazilian Symposium on Operations Research organized by the Brazilian Society of Operational Research (SOBRAPO)) and OPTIMA (Chilean Congress on Operations Research organized by the Chilean Institute of Operations Research (ICHIO)). With this purpose and since there are a lot of universities in the city of Lima (the population is nearly 8 million people), in January 2009, the SOPIOS invited different national universities (Universidad Nacional de Ingeniería, Universidad Nacional del Callao, UNMSM) and private universities (Universidad de Lima, Universidad Ricardo Palma, Universidad de Ciencias Aplicadas, Pontificia Universidad Católica del Perú, Universidad Inca Garcilaso de la

Figure 1. XIII ELAVIO, February 2008.

Figure 2. Conference of Milan Zeleny, June 2008.

Vega) to organize the congress. The Faculty of Industrial Engineering of the UNMSM, was proposed to be the organizer of the Peruvian Congress on Operations Research and Systems (COPIOS 2009), which was accepted by the directive committee of SOPIOS.

COPIOS 2009, will be held in November, and the objective of the congress is not limited to the diffusion and transmission of knowledge, but rather to also attempt to integrate the academia with the industry and services, and the government, so as to foster a sustained development of the OR, systems, and related areas, with benefits for the managerial sector as well as the academic, and for the feedback of knowledge and experiences that could be utilized in both directions. This congress is being sponsored by UNMSM and national organizations such as CONCYTEC, colegio de Ingenieros del Perú, Ministerio de Transporte y Comunicaciones, Sociedad Nacional de Industrias, Pontificia Universidad Católica del Perú, Universidad Nacional del Callao, Universidad Andina del Cusco, Diario la Primera, and international organizations such as IEEE and CLEI. The publicity given to this congress has been to such an extent in the national and international levels, that we will have conference coordinators of the first order, such as Tomas Leibling, Nelson Maculan, Phillipe Michelon, Ann Marie Maculan, and Irene Loiseau.

PERSPECTIVES

At present, the number of associates has increased to 56 members; they are professors

of the universities: Pontificia Universidad Católica del Peru, Universidad Nacional del Callao, and UNMSM (Faculty of Industrial Engineering). However, it is expected that with the congress to be held in November 2009, other professionals and professors of other universities in the interior of Peru will be integrated.

SOPIOS hopes to congregate professionals and academics from the different regions of the country (universities and institutions) so as to become a representative institution that is able to promote the development of OR, systems, and related areas, as much as possible, in each region of Peru.

SOPIOS hopes to integrate the organizations ALIO and IFORS, as representative members of Peru, for which, we have already begun requesting enrolment of applicants at the end of the 2008.

We hope to get closer to our regional partners, so that we can make combined activities for the promotion, dissemination, and application of OR to the problems that our countries face. Finally, we hope to get closer with our nonregional partners also.

SOFTWARE FOR NONLINEARLY CONSTRAINED OPTIMIZATION

SVEN LEYFFER

ASHUTOSH MAHAJAN

Mathematics and Computer Science

Division, Argonne National Laboratory,
Argonne, Illinois

INTRODUCTION AND BACKGROUND

Software for nonlinearly constrained optimization (NCO) tackles problems of the form

$$\begin{cases} \underset{x}{\text{minimize}} & f(x) \\ \text{subject to} & l_c \leq c(x) \leq u_c \\ & l_A \leq A^T x \leq u_A \\ & l_x \leq x \leq u_x, \end{cases} \quad (1)$$

where the objective function $f: \mathbb{R}^n \rightarrow \mathbb{R}$ and the constraint functions $c_i: \mathbb{R}^n \rightarrow \mathbb{R}$, for $i = 1, \dots, m$ are twice continuously differentiable. The bounds $l_c, l_A, l_x, u_c, u_A, u_x$ can be either finite or infinite. Equality constraints are modeled by setting $l_j = u_j$ for some index j . Maximization problems can be solved by multiplying the objective by -1 (most solvers handle this transformation internally). Solvers often take advantage of special constraints such as simple bounds and linear constraints.

NCO solvers are typically designed to work well for a range of other optimization problems such as solving a system of nonlinear equations (most methods reduce to Newton's method in this case), bound-constrained problems, and linear programming (LP) or quadratic programming (QP) problems. In this survey, we concentrate on solvers that can handle general NCO problems possibly involving nonconvex functions. There is software such as MOSEK [1] and CVXOPT [2] that are designed specifically for problems with only convex functions.

Methods for solving Equation (1) are iterative. That is, given an estimate x_0 of the solution, they compute a sequence of iterates $\{x_k\}$ converging to a stationary point, using the following four basic components:

1. *Approximate Subproblem.* The subproblem is an approximation of Equation (1) around the current iterate x_k that can be solved (approximately), and produces a step or search direction that improves the current estimate x_k . Examples of such subproblems are linear or QP approximation, the barrier problem, and an augmented Lagrangian; see the article titled **Foundations of Constrained Optimization**.
2. *Global Convergence Strategy.* The (local) subproblem alone cannot guarantee convergence to a stationary point and optimization methods need a convergence strategy that forces the sequence $\{x_k\}$ to converge. Examples of convergence strategies are penalty functions, augmented Lagrangian, filter and funnel methods; see the article titled **Foundations of Constrained Optimization**.
3. *Global Convergence Mechanism.* The global convergence strategy is enforced by using a mechanism that improves the subproblem by shortening the step that is computed. There are two classes of convergence mechanism: line search and trust region.
4. *Convergence Test.* A convergence test is needed to stop the algorithm once the error in the Karush–Kuhn–Tucker (KKT) (or Fritz–John (FJ)) conditions is below a user-specified tolerance. In addition, solvers may converge only to a local minimum of the constraint violation.

Solvers for NCO are differentiated by how each of these key ingredients is implemented. In addition there are a number of

secondary distinguishing factors such as licensing (open-source versus commercial or academic), API and interfaces to modeling languages, sparse or dense linear algebra, programming language (Fortran/C/MATLAB), and compute platforms on which a solver can run.

The next sections list some solvers for NCOs, summarizing their main characteristics. A short overview can be found in Table 1. We distinguish solvers by the definition of

their subproblem. An alternative characterization could be based on the way in which solvers handle constraints.

INTERIOR-POINT SOLVERS

Interior-point methods approximately solve a sequence of perturbed KKT systems, driving a barrier parameter to zero. Interior-point methods can be regarded as perturbed

Table 1. NCO Software Overview

Name	Model	Global Method	Interfaces	Language
ALGENCAN	Augmented Lagrangian	Penalty	AMPL, C/C++, CUTer, Java, Matlab, Octave, Python, R	f77
CONOPT	GRG/SLQP	Line search	AIMMS, GAMS	Fortran
FilterSQP	SQP	Filter/trust region	AMPL, CUTer, f77	Fortran 77
GALAHAD	Augmented Lagrangian	Nonmonotone/augmented Lagrangian	CUTer, fortran	Fortran95
Ipfilter	IPM	Filter/line search	AMPL, CUTer, f90	Fortran 90
IPOPT	IPM	Filter/line search	AMPL, CUTer, C, C++, f77	C++
KNITRO	IPM	Penalty/trust region line search	AIMMS, AMPL, GAMS, Mathematica, MATLAB, MPL, C, C++, f77, Java, Excel	C
KNITRO	SLQP	Penalty/trust region	s.a.	C
LANCELOT	Augmented Lagrangian	augmented Lagrangian/trust region	SIF, AMPL, f77	f77
LINDO	GRG/SLP	Only convex	C, MATLAB, LINGO	
LOQO	IPM	Line search	AMPL, C, MATLAB	C
LRAMBO	SQP	ℓ_1 exact penalty/line search	C	C/C++
NLPQLP	SQP	Augmented Lagrangian/line search	C, f77, MATLAB	f77
MINOS	Augmented Lagrangian	None	AIMMS, AMPL, GAMS, MATLAB, C, C++, f77	f77
PATH	LCP	Line search	AMPL	C
PENNON	Augmented Lagrangian	Line search	AMPL, MATLAB	C
NPSOL	SQP	Penalty Lagrangian/line search	AIMMS, AMPL, GAMS, MATLAB, C, C++, f77	f77
SNOPT	SQP	Penalty Lagrangian/line search	AIMMS, AMPL, GAMS, MATLAB, C, C++, f77	f77
SQPlab	SQP	Penalty Lagrangian/line search	MATLAB	MATLAB

Newton methods applied to the KKT system in which the primal/dual variables are kept positive.

Ipfilter

Algorithmic Methodology. Ipfilter is based on the interior-point filter method of Ulbrich *et al.* [3]. A step is first generated by solving the normally used KKT system. It then uses a specially designed filter for selecting the step size in the direction of the calculated step. The first component of the filter is the sum of “constraint violation” and “centrality,” while the second component is the norm of the gradient of the Lagrangian. This method can sometimes converge to a local maximum because the filter does not explicitly check the objective function value. In the implementation of Ipfilter, the second component of the filter is modified to overcome this problem [4].

Software and Technical Details. Ipfilter version 0.3 is written in Fortran90. It requires a user to have MA57 routine from the HSL library. Ipfilter is available at no cost for academic purposes and can be obtained by contacting the developers at the Ipfilter web page [5]. It has interfaces in AMPL and CUTEr. The user can also write their own functions and derivatives in Fortran90.

IPOPT

Algorithmic Methodology. IPOPT is a line-search filter interior-point method [6–8]. The outer loop approximately minimizes a sequence of nonlinearly (equality-) constrained barrier problems for a decreasing sequence of barrier parameters. The inner loop uses a line-search filter SQP method to approximately solve each barrier problem. Global convergence of each barrier problem is enforced through a line-search filter method, and the filter is reset after each barrier parameter update. Steps are computed by solving a primal–dual system, corresponding to the KKT conditions of the barrier problem. The algorithm controls the inertia of this system by adding δI ($\delta > 0$) to the Hessian of the Lagrangian, ensuring descent properties. The inner iteration includes second-order correction steps and mechanisms for switching to a feasibility

restoration if the step size becomes too small. The solver has an option for using limited-memory BFGS updates to approximate the Hessian of the Lagrangian.

Software and Technical Details. The solver is written in C++ and has interfaces to C, C++, Fortran, AMPL, CUTEr, and COIN-OR’s NLPAPI. It requires BLAS, LAPACK, and a sparse indefinite solver (MA27, MA57, PARDISO, or WSMP). The user (or the modeling language) must provide function and gradient information, and possibly the Hessian of the Lagrangian (in sparse format). By using the PARDISO [9] parallel linear solver, IPOPT can solve large problems on shared-memory multiprocessors. IPOPT is available on COIN-OR under Common Public License at its website [10].

KNITRO

KNITRO includes both IPM and SLQP methods. The IPM version is described in this section.

Algorithmic Methodology. KNITRO implements both trust region–based and line-search-based interior-point/barrier methods [11–13]. It approximately solves a sequence of barrier subproblems for a decreasing sequence of barrier parameters. It uses a merit or a penalty function for accepting a step and for ensuring global convergence. The barrier subproblems are solved by a sequence of linearized primal–dual equations. KNITRO has two options for solving the primal–dual system: direct factorization of the system of equations and preconditioned conjugate-gradient (PCG) method. The PCG method solves the indefinite primal–dual system by projecting onto the null space of the equality constraints. KNITRO also includes modules for solving mixed-integer nonlinear optimization problems and optimization problems with simple complementarity constraints. In addition, it contains crossover techniques to obtain an active set from the solution of the IPM solve and a multistart heuristic for nonconvex NCOs.

Software and Technical Details. KNITRO is written in C. It has interfaces to a range

of modeling languages, including AIMMS, AMPL, GAMS, Mathematica, MATLAB, and MPL. In addition, KNITRO has interfaces to C, C++, Fortran, Java, and Excel. It offers callback and reverse communication interfaces. KNITRO makes use of MA27/MA57 to solve the indefinite linear systems of equations, and these routines are included in the package. KNITRO is available from Ziena Optimization, Inc., and the user's manual is available on-line [14].

LOQO

Algorithmic Methodology. LOQO [15] uses an infeasible primal–dual interior-point method for solving general nonlinear problems. The inequality constraints are added to the objective by using a log-barrier function. Newton's method is used to obtain a solution to the system of nonlinear equations that is obtained by applying first-order necessary conditions to this barrier function. The solution of this system provides a search direction, and a filter or a merit function is used to accept the next iterate obtained by performing a line search in this direction. The filter is specially modified for interior-point methods [16]. It allows a point that improves either the feasibility or the barrier objective as compared to the current iterate only. The merit function is the barrier function and an additional ℓ_2 norm of the violation of constraints. The exact Hessian of the Lagrangian is used in the Newton's method. When the problem is nonconvex, this Hessian is perturbed by adding to it the matrix δI , where I is an identity matrix and $\delta > 0$ is chosen so that the perturbed Hessian is positive definite. This perturbation ensures that if the iterates converge, they converge to a local minimum. LOQO can also handle complementarity constraints by using a penalty function [17].

Software and Technical Details. LOQO can be used to solve problems written in AMPL. The user can also implement functions in C and link to the LOQO library. LOQO can also read files in MPS format for solving LPs. A MATLAB interface for LOQO is available for LPs, QPs, and second-order cone programs. The library and binary files are

available for a license fee at its homepage [18], while a limited student version is available freely. A user manual provides instructions on installing and using LOQO.

SEQUENTIAL LINEAR/QUADRATIC SOLVERS

Sequential linear/quadratic solvers solve a sequence of LP and/or QP subproblems. This class of solvers is also referred to as active-set methods, because they provide an estimate of the active set at every iteration. Once the active set settles down, these methods become Newton methods on the active constraints (except SLP).

CONOPT

Algorithmic Methodology. CONOPT [19,20] implements three active-set methods. The first is a gradient projection method that projects the gradient of the objective onto a linearization of the constraints and makes progress toward the solution by reducing the objective. The second variant is an SLP method, and the third is an SQP method. CONOPT includes algorithmic switches that automatically detect which method is preferable. It also exploits triangular parts of the Jacobian matrix and linear components of the Jacobian to reduce the sparse factorization overhead. CONOPT is a line-search method.

Software and Technical Details. CONOPT has interfaces to AMPL, GAMS, and AIMMS and is available from any of the three companies.

FilterSQP

Algorithmic Methodology. FilterSQP [21] implements a trust-region SQP method. Convergence is enforced with a filter, whose components are the ℓ_1 -norm of the constraint violation, and the objective function. The solver starts by projecting the user-supplied initial guess onto the linear part of the feasible set and remains feasible with respect to the linear constraints. It uses an indefinite QP solver that finds local solutions to problems with negative curvature. The solver switches to a feasibility restoration phase

if the local QP model becomes inconsistent. During the restoration phase, a weighted sum of the constraint violations is minimized by using a filter SQP trust-region approach. The restoration phase either terminates at a local minimum of the constraint violation or returns to the main algorithm when a feasible local QP model is found. FilterSQP computes second-order correction steps if the QP step is rejected by the filter.

Software and Technical Details. The solver is implemented in Fortran77 and has interfaces to AMPL, CUTer, and Fortran77. The code requires subroutines to evaluate the problem functions, their gradients, and the Hessian of the Lagrangian (provided by AMPL and CUTer). It uses BQPD [22] to solve the possibly indefinite QP subproblems. BQPD is a null-space active-set method and has modules for sparse and dense linear algebra with efficient and stable factorization updates. The code is licensed by the University of Dundee.

KNITRO

Algorithmic Methodology. In addition to the interior-point methods (see the section titled “KNITRO” of the section titled “Interior-Point Solver”), KNITRO implements an SLQP algorithm [23,24]. In each iteration, an LP that approximates the ℓ_1 exact-penalty problem is solved to determine an estimate of the active set. This LP also has an additional infinity-norm trust-region constraint. Those constraints in the LP that are satisfied as equalities are marked as active and are used to set up an equality-constrained quadratic programming (EQP), whose objective is a quadratic approximation of the Lagrangian of Equation (1) at the current iterate. An ℓ_2 -norm trust-region constraint is also added to this QP. The solution of the LP and the EQP are then used to find a search direction [13,24]. A projected conjugate-gradient method is used to solve the EQP. The penalty parameter ρ_k is updated to ensure sufficient decrease toward feasibility.

Software and Technical Details. The SLQP method of KNITRO requires an LP solver.

KNITRO includes CLP as well as a link to CPLEX as options. For other details, the section titled “KNITRO” of the section titled “Interior-Point Solver”. This active-set algorithm is usually preferable for rapidly detecting infeasible problems and for solving a sequence of closely related problems.

LINDO

Algorithmic Methodology. LINDO provides solvers for a variety of problems including NCOs. Its nonlinear solver implements an SLP algorithm and a generalized gradient method. It provides options to randomly select the starting point and can estimate derivatives by using finite differences.

Software and Technical Details. LINDO [25] provides interfaces for programs written in languages such as C and MATLAB. It can also read models written in LINGO. The full version of the software can be bought on-line, and a limited trial version is available for free [26].

LRAMBO

Algorithmic Methodology. LRAMBO is a *total quasi-Newton* SQP method. It approximates both the Jacobian and the Hessian by using rank-1 quasi-Newton updates. It enforces global convergence through a line search on an ℓ_1 exact-penalty function. LRAMBO requires as input only an evaluation program for the objective and the constraints. It combines automatic differentiation (AD) and quasi-Newton updates to update factors of the Jacobian. And it computes updates of the Hessian. Details can be found in Griewank *et al.* [27].

Software and Technical Details. LRAMBO uses the NAG subroutine E04NAF to solve the QP subproblems. It also requires ADOL-C [28,29] for the AD of the problem functions. LRAMBO is written in C/C++.

NLPQLP

Algorithmic Methodology. NLPQLP is an extension of the SQP solver NLPQL [30] that

implements a nonmonotone line search to ensure global convergence. It uses a quasi-Newton approximation of the Hessian of the Lagrangian, which is updated with the BFGS formula. A nonmonotone line search is used to calculate the step length that minimizes an augmented Lagrangian merit function.

Software and Technical Details. NLPQLP is implemented in Fortran. The user or the interface is required to evaluate the function values of the objective and constraints. Derivatives, if unavailable, can be estimated by using finite differences. NLPQLP can evaluate these functions and also the merit function on a distributed memory system. A user guide with documentation, algorithm details, and examples is available [31]. NLPQLP can be obtained under academic and commercial license from its website.

NPSOL

Algorithmic Methodology. NPSOL [32] solves general nonlinear problems by using an SQP algorithm with a line search on the augmented Lagrangian. In each major iteration, a QP subproblem is solved whose Hessian is a quasi-Newton approximation of the Hessian of the Lagrangian using a *dense* BFGS update.

Software and Technical Details. NPSOL is implemented in Fortran, and the library can be called from Fortran and C programs and from modeling languages such as AMPL, GAMS, AIMMS, and MATLAB. The user or the interface must provide routines for evaluating functions and their gradients. If a gradient is not available, NPSOL can estimate it by using finite differences. It treats all matrices as dense and hence may not be efficient for large-sparse problems. NPSOL can be warm started by specifying the active constraints and multiplier estimates for the QP. NPSOL is available under commercial and academic licenses from Stanford Business Software Inc.

PATHNLP

Algorithmic Methodology. PATH [33,34] solves mixed complementarity problems

(MCPs). PATHNLP automatically formulates the KKT conditions of an NLP, Equation (1), specified in GAMS as an MCP and then solves this MCP using PATH. The authors note that this approach is guaranteed only to find stationary points and does not distinguish between local minimizers and maximizers for nonconvex problems. Thus, it works well for convex problems. At each iteration, PATH solves a linearization of the MCP problem to obtain a Newton point. It then performs a search in the direction of this point to find a minimizer of a merit function. If this direction is not a descent direction, it performs a steepest descent step in the merit function to find a new point.

Software and Technical Details. The PATHNLP is available only through GAMS [35]. The PATH solver is implemented in C and C++ [36].

SNOPT

Algorithmic Methodology. SNOPT [37] implements an SQP algorithm much like NPSOL, but it is suitable for large, sparse problems as well. The Hessian of the Lagrangian is updated by using limited-memory quasi-Newton updates. SNOPT solves each QP using SQOPT [38], which is a reduced-Hessian active-set method. It includes an option for using a projected conjugate-gradient method rather than factoring the reduced Hessian. SNOPT starts by solving an “elastic program” that minimizes the constraint violation of the linear constraints of Equation (1). The solution to this program is used as a starting point for the major iterations. If a QP subproblem is found to be infeasible or unbounded, then SNOPT tries to solve an elastic problem that corresponds to a smooth reformulation of the ℓ_1 exact-penalty function. The solution from a major iteration is used to obtain a search direction along which an augmented Lagrangian merit function is minimized.

Software and Technical Details. SNOPT is implemented in Fortran77 and is compatible with newer Fortran compilers. All functions

in the SNOPT library can be used in parallel or by multiple threads. It can be called from other programs written in C and Fortran and by packages such as AMPL, GAMS, AIMMS, and MATLAB. The user or the interface has to provide routines that evaluate function values and gradients. When gradients are not available, SNOPT uses finite differences to estimate them. SNOPT can also save basis files that can be used to save the basis information to warm start subsequent QPs. SNOPT is available under commercial and academic licenses from Stanford Business Software Inc.

SQPlab

Algorithmic Methodology. SQPlab [39] was developed as a laboratory for testing algorithmic options of SQP methods [40]. SQPlab implements a line-search SQP method that can use either exact Hessians or a BFGS approximation of the Hessian of the Lagrangian. It maintains positive definiteness of the Hessian approximation using the Wolfe or Powell condition. SQPlab uses a Lagrangian penalty function, $p_\sigma(x, y) = f(x) + y_c^T c(x) + \sigma \| \max\{0, c(x) - u_c, l_c - c(x)\} \|_1$, to promote global convergence. SQPlab has a feature that allows it to treat discretized optimal control constraints specially. The user can specify a set of equality constraints whose Jacobian has uniformly full rank (such as certain discretized optimal-control constraints). SQPlab then uses these constraints to eliminate the state variables. The user needs to provide only routines that multiply a vector by the inverse of the control constraints.

Software and Technical Details. SQPlab is written in MATLAB and requires `quadprog.m` from the optimization toolbox. The user must provide a function simulator to evaluate the functions and gradients. A smaller version is also available that does not require `quadprog.m` but instead uses `qpal.m`, an augmented Lagrangian QP solver for medium-sized convex QPs. All solvers are distributed under the Q public license from INRIA, France [41].

AUGMENTED LAGRANGIAN SOLVERS

Augmented Lagrangian methods solve Equation (1) by a sequence of subproblems that minimize the augmented Lagrangian, either subject to a linearization of the constraints or as a bound-constrained problem.

ALGENCAN

Algorithmic Methodology. ALGENCAN is a solver based on an augmented Lagrangian-type algorithm [42,43] in which a bound-constrained problem is solved in each iteration. The objective function in each iteration is the augmented Lagrangian of the original problem. This subproblem is solved by using a quasi-Newton method. The penalty on each constraint is increased if the previous iteration does not yield a better point.

Software and Technical Details. ALGENCAN is written in Fortran77, and interfaces are available for AMPL, C/C++, CUTer, JAVA, MATLAB, Octave, Python, and R. The bound-constrained problem in each iteration is solved by using GENCAN, developed by the same authors. ALGENCAN and GENCAN are freely available under the GNU Public License from the TANGO project web page [44].

GALAHAD

Algorithmic Methodology. GALAHAD [45] contains a range of solvers for large-scale nonlinear optimization. It includes LANCELOT B, an augmented Lagrangian method with a nonmonotone descend condition; FILTRANE, a solver for feasibility problems based on a multidimensional filter [46]; and interior-point and active-set methods for solving large-scale quadratic programs (QPs). GALAHAD also contains a presolve routine for QPs [47] and other support routines.

Software and Technical Details. GALAHAD is a collection of thread-safe Fortran95 packages for large-scale nonlinear optimization. It is available in source form at <http://galahad.rl.ac.uk/> [48]. GALAHAD has links to CUTer and Fortran.

LANCELOT

Algorithmic Methodology. LANCELOT [49] is a large-scale implementation of a bound-constrained augmented Lagrangian method. It approximately solves a sequence of bound-constrained augmented Lagrangian problems by using a trust-region approach. Each trust-region subproblem is solved approximately: first, the solver identifies a Cauchy-point to ensure global convergence, and then it applies conjugate-gradient steps to accelerate the local convergence. LANCELOT provides options for a range of quasi-Newton Hessian approximations suitable for large-scale optimization by exploiting the group-partial separability of the problem functions.

Software and Technical Details. LANCELOT is written in standard ANSI Fortran77 and has been interfaced to CUTer [50] and AMPL. The distribution includes installation scripts for a range of platforms in single and double precision. LANCELOT is available freely from Rutherford Appleton Laboratory, UK [51].

MINOS

Algorithmic Methodology. MINOS [52] uses a projected augmented Lagrangian for solving general nonlinear problems. In each “major iteration,” a linearly constrained nonlinear problem is solved where the linear constraints constitute all the linear constraints of Equation (1) and also linearizations of nonlinear constraints. This problem is in turn solved iteratively by using a reduced-gradient algorithm along with a quasi-Newton algorithm. The quasi-Newton algorithm provides a search direction along which a line search is performed to improve the objective function and reduce the infeasibilities. MINOS does not guarantee convergence from a remote starting point. The user should therefore specify a starting point that is “close enough” for convergence. This issue will be addressed in a new software Knossos that will use a stabilized version of the linearly constrained Lagrangian method [53]. The user can also modify other parameters such as the penalty parameter

in augmented Lagrangian to control the algorithm.

Software and Technical Details. MINOS is implemented in Fortran. The library can be called from Fortran and C programs and interfaces such as AMPL, GAMS, AIMMS, and MATLAB. The user must input routines for the function and gradient evaluations. If a gradient is not available, MINOS estimates it by using finite differences. MINOS is available under commercial and academic licenses from Stanford Business Software Inc.

PENNON

Algorithmic Methodology. PENNON [54] is an augmented Lagrangian penalty-barrier method. In addition to standard NCOs, it can handle semidefinite NCOs that *include a semidefiniteness constraint on matrices of variables*. PENNON represents the semidefiniteness constraint by computing an eigenvalue decomposition and adds a penalty-barrier for each eigenvalue to the augmented Lagrangian. It solves a sequence of unconstrained optimization problems in which the inequality constraints appear in barrier functions and the equality constraints in penalty functions. Every unconstrained minimization problem is solved with Newton’s method. The solution of this problem provides a search direction along which a suitable merit function is minimized. Even though the algorithm has not been shown to converge for nonconvex problems, it has been reported to work well for several problems.

Software and Technical Details. PENNON can be called from either AMPL or MATLAB. The user manual [55] provides instructions for input of matrices in sparse format when using AMPL. PENNON includes both sparse factorizations using the algorithm of Ng and Peyton [56] and dense factorization using LAPACK. Commercial licenses and a free academic license are available from PENOPT-GbR.

TERMINATION OF NCO SOLVERS

Solvers for NCOs can terminate in a number of ways. Normal termination

corresponds to a KKT point, but solvers can also detect (locally) infeasible NCOs and unboundedness. Some solvers also detect failure of constraint qualifications. Solvers also may terminate because of errors, and we provide some simple remedies.

Normal Termination at KKT Points

Normal termination corresponds to termination at an approximate KKT point, that is, a point at which the norm of the constraint violation, the norm of the first-order necessary conditions, and the norm of the complementary slackness condition are less than a user-specified tolerance. Some solvers divide the first-order conditions by the modulus of the largest multiplier. If the problem is convex (and feasible), then the solution corresponds to a global minimum of Equation (1). Many NCO solvers include sufficient decrease conditions that make it less likely to converge to local maxima or saddle points if the problem is nonconvex.

Termination at Other Critical Points

Unlike LP solvers, NCO solvers do not guarantee global optimality for general nonconvex NCOs. Even deciding whether a problem is feasible or unbounded corresponds to a global optimization problem. Moreover, if a constraint qualification fails to hold, then solvers may converge to critical points that do not correspond to KKT points.

Fritz–John (FJ) Points. This class of points corresponds to first-order points at which a constraint qualification may fail to hold. NCO solvers adapt their termination criterion by dividing the stationarity condition by the modulus of the largest multiplier. This approach allows convergence to FJ points that are not KKT points. We note that dividing the first-order error is equivalent to scaling the objective gradient by a constant $0 \leq \alpha \leq 1$. As the multipliers diverge to infinity, this constant converges to $\alpha \rightarrow 0$, giving rise to an FJ point.

Locally Inconsistent Solutions. To prove that an NCO is locally inconsistent requires the (local) solution of a feasibility problem,

in which a norm of the nonlinear constraint residuals is minimized subject to the linear constraints. A KKT point of this problem provides a certificate that Equation (1) is locally inconsistent. There are two approaches to obtaining this certificate. Filter methods switch to a feasibility restoration phase if either the stepsize becomes too small or the LP/QP subproblem becomes infeasible. Penalty function methods do not switch but drive the penalty parameter to infinity.

Unbounded Solutions. Unlike the case of LP where a ray along the direction of descent is necessary and sufficient to prove that the instance is unbounded, it is difficult to check whether a given nonlinear program is unbounded. Most NCO solvers use a user-supplied lower bound on the objective and terminate if they detect a feasible point with a lower objective value than the lower bound.

Remedies If Things Go Wrong

If a solver stops at a point where the constraint qualifications appears to fail (indicated by large multipliers) or where the nonlinear constraints are locally inconsistent or at a local and not global minimum, then one can restart the solver procedure from a different initial point. Some solvers include automatic random restarts.

Another cause for failure is errors in the function, gradient, or Hessian evaluation (e.g., IEEE exceptions). Some solvers provide heuristics that backtrack if IEEE exceptions are encountered during the iterative process. In many cases, IEEE exceptions occur at the initial point, and backtracking cannot be applied. It is often possible to reformulate the nonlinear constraints to avoid IEEE exceptions. For example, $\log(x_1^3 + x_2)$ will cause IEEE exceptions if $x_1^3 + x_2 \leq 0$. Adding the constraint $x_1^3 + x_2 \geq 0$ does not remedy this problem, because nonlinear constraints may not be satisfied until the limit. A better remedy is to introduce a nonnegative slack variable, $s \geq 0$ and the constraint $s = x_1^3 + x_2$, and then replace $\log(x_1^3 + x_2)$ by $\log(s)$. Many NCO solvers will honor simple bounds (and interior-point solvers guarantee $s > 0$), so this formulation avoids some IEEE exceptions.

CALCULATING DERIVATIVES

All solvers described above expect either the user or the modeling environment (AMPL, GAMS, etc.) to provide first-order and sometimes second-order derivatives. Some solvers can estimate first-order derivatives by finite differences. If the derivatives are not available or if their estimates are not reliable, one can use several AD tools that are freely available. We refer the readers to Griewank [57] for principles and methods of AD and to More [58] for using AD in nonlinear optimization. AD tools include ADOL-C [29]; ADIC, ADIFOR, and OpenAD [59]; and Tapenade [60].

WEB RESOURCES

In addition to a range of NCO solvers that are available on-line, there exist an increasing number of web-based resources for optimization. The NEOS server for optimization [61,62] allows users to submit optimization problems through a web interface, using a range of modeling languages. It provides an easy way to try out different solvers. The NEOS wiki [63] provides links to optimization case studies and background on optimization solvers and problem classes. The COIN-OR project [64] is a collection of open-source resources and tool for operations research, including nonlinear optimization tools (IPOPT and ADOL-C). A growing list of test problems for NCOs includes the CUTer collection [65], Bob Vanderbei's collection of testproblems [66], the COPS testset [67], and the GAMS model library [68]. The NLP-FAQ [69] provides on-line answers to questions on nonlinear optimization.

SOFTWARE FOR SOLVING NONCOOPERATIVE STRATEGIC FORM GAMES

THEODORE L. TUROCY
School of Economics,
University of East Anglia,
Norwich, UK

INTRODUCTION AND OVERVIEW

Game theory is an elegant tool for modeling and analyzing strategic interaction among multiple agents. Over the last half-century, it has proven its worth and flexibility across disciplines from economics to computer science to operations research. This flexibility comes with some costs. It can be unwieldy to write down a formal specification of a noncooperative strategic form game, even for relatively small numbers of players and strategies available to those players. Furthermore, once the game is specified, computing predictions for how the game will or ought to be played, especially the Nash equilibrium (or equilibria) of the game, is tedious to do by hand for even small games, and completely impractical for games of moderate size. To move beyond toy examples and investigate models that are useful in operations and management contexts, software tools for specifying and solving noncooperative strategic form games are essential.

The good news for the practitioner interested in solving particular games is that the Nash equilibrium of a game can be formulated in terms of a variety of mathematical programming problems. These programming problems, in turn, can be solved using a combination of off-the-shelf general-purpose libraries, as well as implementations that may take advantage of the special structure of the programming problems that arise specifically from games.

This article first gives a high-level overview of Gambit, an integrated package

for doing computation on finite games. The main body of the article provides a “field guide” to computing equilibria. This guide mixes an overview of the available algorithms and implementations with general advice on techniques and reasonable expectations for solving games. In a brief conclusion, some current and anticipated future directions for research in this area over the next few years are highlighted.

GAMBIT

The most comprehensive package available for computing Nash equilibria in finite games is Gambit, available at <http://www.gambit-project.org>. The Gambit project offers a unified suite of tools for working with finite games, available for Windows, OS X, and Linux. Gambit is fully open source, and is licensed under the GNU GPL.

The Gambit project was initiated in the early 1990s by Richard McKelvey and developed extensively in the mid-1990s via a National Science Foundation grant to McKelvey and Andrew McLennan. The impetus behind the conception of the project was to provide a framework for developing and manipulating representations of finite games in extensive and strategic form, and providing implementations of the emerging array of algorithms for computing Nash equilibria and other solution concepts for games to researchers, students, and practitioners.

For most users, the front door to Gambit is the graphical user interface. This tool offers the ability to construct games of small to medium size interactively, including the specification of players, move structures, information structures, and payoffs. The interface also allows for the interactive elimination of dominated strategies and actions and conversion of an extensive game to its reduced strategic form equivalent. Finally, it serves as a front end to the implementation of methods for computing

one or more Nash equilibria of the game, and for inspecting the implications of the resulting equilibria.

As of this writing in early 2010, Gambit is set for a significant overhaul. The current architecture of Gambit dates back to the mid-1990s, and is written primarily in C++. The architecture is modular, in that there is a self-contained library for representing games, entities within games such as players and outcomes, and concepts related to games such as mixed strategy profiles. Each algorithm for computing Nash equilibria in games is implemented separately, and wrapped as a stand-alone command-line tool for external scripting use. This current architecture makes Gambit modestly scriptable.

The state of the architecture also reflects the time at which it was written. In the mid-1990s, the term *open source* had yet to be coined officially, and libraries for scientific computing with licenses that encouraged reuse and redistribution were few. In addition, advances in computing power and algorithmic development have significantly expanded the scope of the type and size of game that can be analyzed using off-the-shelf hardware. The planned next iteration of Gambit will rebuild the architecture to be more friendly to modern scripting languages like Python, and to interface more cleanly with other tools relevant to the practice of game theory and scientific computing. Several of these changes are already available on an experimental basis in the current version. In addition, the current Gambit architecture represents all games by an explicit table of payoffs in memory. Decreases in the cost of computation, combined with improvements in algorithms, have now made more ambitious computational projects feasible. For example, one might explore numerically how equilibrium predictions depend on a parameter such as a player's attitude toward risk. When analyzing such a family of games, customized calculation of payoffs can offer significant advantages in representation space, and in running times. Future iterations of Gambit will offer facilities for supporting programming

game representations targeted at specific applications.

In the discussion in this article, the focus is on general-purpose tips on how to go about solving finite games. The organization will generally follow the structure of tools available in Gambit. Where other software resources exist that are not well-integrated into the Gambit framework, these will also be indicated.

FIELD GUIDE TO SOLVING GAMES

The first piece of advice for the practitioner interested in computing Nash equilibria in finite games is to have reasonable expectations. Computing a Nash equilibrium is algorithmically a challenging problem; see, for instance, Daskalakis *et al.* [1] and the references therein. In addition, there may be many Nash equilibria of a game (for example, McKelvey and McLennan [2]). Taken together, these imply that games that do not seem to be particularly large at first glance may be surprisingly difficult to solve. This suggests that a good strategy in approaching a game-theoretic model in a field application is to begin with a simple game structure.

Basic results in game theory show that the set of Nash equilibria is a subset of the strategy profiles that survive iterated elimination of strictly dominated strategies. Because running times are exponential in the number of strategies in the game, it is valuable to reduce the number of strategies being considered, whenever possible. Experience indicates checking for and eliminating dominated strategies pays off on average in improved overall running times. Gambit offers routines for automating this process.

The focus of this article is on solving games in strategic form. Historically, methods for computing equilibria in the strategic form of a game were well developed earlier. The last decade has seen significant algorithmic advancements in computing equilibria in extensive games (e.g., the sequence form of Koller *et al.* [3]). The representation of a game in extensive form is generally smaller than its strategic form counterpart, particularly when players have many information

sets in the extensive version of the game. When possible, consider using an algorithm that exploits the extensive structure of the game; the discussion in this article indicates where extensive form versions of equilibrium computation methods exist.

Complexity results such as the ones cited above are worst-case guarantees. Many games of interest in practice may have structure that can be exploited. The researcher may have prior beliefs that an equilibrium of a certain type might exist, or might be interested primarily in equilibria involving certain actions being played. Organizing the search for equilibria around this knowledge can help speed up the determination of answers to specific research questions, rather than waiting on an exhaustive analysis of the set of equilibria. There has been recent research in the direction of using heuristics to optimize the time to compute one Nash equilibrium.

For any game, an excellent place to begin the analysis is a simple enumeration of pure strategy equilibria. While the number of possible pure strategy profiles increases exponentially in the size of the game, checking whether a given strategy profile is a Nash equilibrium is in practice fast, and since it is a brute-force search, it is straightforward to parallelize. The rest of this section gives an overview of the available tools for computing Nash equilibria in general, including those involving mixed strategies. These methods divide into those that are applicable for games with two players and those that are applicable for games with arbitrary numbers of players. We now turn to each of those classes individually.

Two-Player Games

In a strategic form game with two players, the expected payoff to each strategy is a linear function of the probabilities that specify the other player's mixed strategy. This special structure admits algorithms for computing the set of Nash equilibria that exploit linearity and convexity. In a general two-player game, the set of Nash equilibria can be expressed as the union of convex sets of mixed strategy profiles. Furthermore, when the game is constant-sum, the set of

equilibria is itself one convex component. In both cases, the extreme points of the convex components are rational numbers when the payoffs specifying the game are rational. Gambit takes the perspective that all payoffs and probabilities in specifying a game are rational.

For two-player constant-sum games, the Nash equilibrium problem can be formulated as a standard linear programming problem (Dantzig [4]). Therefore, any linear programming solver can be brought to bear on computing equilibria. Gambit provides a self-contained linear programming solver in its distribution, wrapped in the command-line tool `gambit-lp`. In addition, there is experimental support for formulating the linear programming problem based on any game and passing the problem to external solvers. Since there are many strong options for both free and commercial linear programming solvers, external solvers may be the appropriate choice for many applications.

For two-player games that are not constant-sum, the equilibrium problem is a linear complementarity problem (Lemke and Howson [5]). There are two approaches to solving the linear complementarity problem. Lemke and Howson provided a linear path-following algorithm based on pivoting, reminiscent of the simplex method for linear programs. Experience has shown that this method, implemented as `gambit-lcp` in the Gambit package, is often efficient in finding an equilibrium of the game. However, the method of Lemke and Howson [5] is not guaranteed to find all equilibria; see Shapley [6] for an example. In addition, Savani and von Stengel [7] show how to construct pathological examples of games in which Lemke–Howson method takes exponentially long to arrive at an equilibrium.

Instead, to guarantee computation of all equilibria, the reverse pivoting algorithm of Avis and Fukuda [8] can be used. This method, implemented in Gambit as `gambit-ennummixed`, systematically enumerates all possible extreme points of the components of the set of equilibria, and determines whether or not they satisfy the Nash equilibrium conditions. An independent implementation of the algorithm, named `lrslib`, has been

made available under the GPL by Avis at <http://cgm.cs.mcgill.ca/~avis/C/lrs.html>. Avis' implementation includes a driver program for using the library to compute the set of Nash equilibria. For access to `lrslib` without the need to download and compile it, Rahul Savani has made a Web-based frontend to `lrslib` for computing equilibria [9]. As of this writing, there is an experimental wrapping of `lrslib` available in the `gambit-ennummixed` tool. The Gambit wrapping is often a version or two behind the latest `lrslib`, and therefore it does not always include the latest features; for instance, the most recent `lrslib` has support for executing the algorithm on multiple processors, which is not yet available via Gambit. A good self-contained resource describing the reverse pivoting algorithm and other recent developments in computing all equilibria of two-player strategic form games is Avis *et al.* [10], which includes a table summarizing how expected running times scale with the number of strategies in the game.

Because both the linear program and the reverse pivoting algorithm are of independent interest outside of their applications to the equilibrium computation problem, external solvers generally offer better support than the native Gambit implementations. One strength of the Gambit native implementation not always found in external solvers is the ability to carry out the entire calculation in exact rational arithmetic. Rational arithmetic is significantly slower than floating-point arithmetic, but pivoting calculations can be done exactly without rounding error, and exact representations of the extreme points of the equilibrium set can be found. While the set of Nash equilibria is a collection of isolated points in general, games that are of interest in practice often have components of equilibria that have positive dimension. Rational arithmetic handles the implied degeneracies exactly. In addition, Gambit offers support in the `gambit-ennummixed` tool for identifying the structure of the equilibrium components.

The existence of positive-dimensional components of equilibria in strategic games often arises because they are the reduced strategic form representations of extensive games.

The sequence form (Koller *et al.* [3]) allows for using linear programming and linear complementarity programming to compute equilibria while exploiting the extensive structure of the game.

General-Player Games

Games with more than two players lack the linear structure in payoffs present in games with only two players. Therefore, the problem of computing equilibria becomes more challenging. The development of effective methods for solving these games has occurred more recently than for two-player games, and remains an active area for further development in algorithms and implementations.

There is one existing method for finding all equilibria in a generic game with more than two players. This method relies on enumerating all the possible supports (sets of strategies played with positive probability) in the game. On a given support, the Nash equilibrium conditions can be expressed as a collection of equalities that are polynomial in the probabilities with which strategies are played, and a collection of inequalities that are also polynomial in the same probabilities. Therefore, for a given support, one can use an external solver to compute all solutions of the system of polynomial equalities, then check the candidate solutions, and keep only those that satisfy the inequalities and form valid probability distributions. A version of this approach was implemented in Gambit by Andrew McLennan ca. 1995, and the algorithm was formally defined and proved correct by Herings and Peeters [11].

Implementations of algorithms for finding the solutions to systems of polynomial equations are a recent development in the field of algebraic geometry. Two leading packages as of this writing are `PHCpack` by Jan Verschelde (at <http://www.math.uic.edu/~jan/download.html>) and `Bertini` by Bates *et al.* (at <http://www.nd.edu/~sommese/bertini/>). Turcoy [12] describes preliminary results of integrating `PHCpack` with Gambit. The experimental interface in Gambit to this method, currently distributed separately from the main Gambit package, also includes support for using `Bertini` as the backend solver.

Carrying out this algorithm is a formidable task, because the number of potential supports is exponential in the number of strategies a player can choose. If player i has k_i strategies, then there are $2^{k_i} - 1$ potential supports for that player, and $\prod_{i=1}^n (2^{k_i} - 1)$ possible supports overall. As Herings and Peeters [11] and Turocy [12] show, many of these supports can be ruled out as candidates by checks that require little processing time, so in practice the number of supports that have to be passed to the polynomial solver is significantly less than the theoretical maximum. In addition, because each support is an independent problem, the solution process is embarrassingly parallelizable; it is straightforward to utilize multiple independent threads of computation if multiple processors are available.

For some applications, exhaustive enumeration of all equilibria may not be necessary. Given that multiplicity of Nash equilibria is the rule rather than the exception, one may simply be interested in obtaining a sample Nash equilibrium. There exist several approaches for computing a single equilibrium of a game, all based on homotopy methods. The leading approaches in this area are surveyed by Herings and Peeters [13]. Loosely speaking, the basic idea behind these methods is, given a game of interest, to construct a sequence of games converging to that game. The sequence is constructed in such a way that the first game in the sequence is easy to solve, perhaps because it has an equilibrium in strictly dominant strategies. Then, because the set of Nash equilibria changes in a continuous way along the sequence of games, it is possible to “trace” an equilibrium back to the original game of interest.

In fact, the path-following algorithm of Lemke and Howson [5] can be interpreted as implementing just such a homotopy, for the special case of two-player games. As noted, the linear structure of expected payoffs in two-player games means that techniques for following the path of equilibria are exactly available. In games with more than two players, numerical procedures must be used to follow generally nonlinear paths

approximately. The Lemke-Howson method is generalized to n -player games by the global Newton method of Govindan and Wilson [14,15]. This has been implemented in the GameTracer package by Blum, Koller, and Shelton, and is available at <http://dags.stanford.edu/Games/gametracer.html>, distributed under the GNU GPL. Gambit incorporates the GameTracer implementation in the gambit-gnm and gambit-ipa command-line tools. The operation of the global Newton method is parameterized by specifying an initial perturbation vector, which specifies how the payoffs of the game are adjusted to find the initial starting game that is easy to solve. The resulting equilibria found by the procedure in general depend on the choice of this initial vector.

This last observation, that the equilibria found by an algorithm are a subset of the full set of equilibria, suggests the idea of selecting from the set of equilibria using an appropriately chosen algorithm. The multiplicity of Nash equilibria has always been a vexing problem in using the concept to predict behavior in a game, and the number of equilibria in a game tends to grow as the number of strategies and number of players are increased. This idea of using an algorithm to systematically select an equilibrium with desirable properties was made explicit in the form of the tracing procedure of Harsanyi [16] and Harsanyi and Selten [17]. The tracing procedure imagines players arriving at a Nash equilibrium of a game by beginning with initial beliefs about how other players will play the game. On the basis of this initial belief, through a process of introspection, the players adjust their intended actions based on their beliefs, while also adjusting their beliefs by realizing that other players are undergoing the same adjustment process. The tracing procedure results in paths that may not be differentiable at some points, thus complicating the numerical implementation of the tracing. Herings and Peeters [18] provide an implementation of an algorithm for following a differentiable path through the space of mixed strategy profiles to find a Nash equilibrium. While the path of strategy profiles followed is not exactly that of the tracing procedure, Herings and Peeters show that the

equilibrium the method computes coincides with the equilibrium selected by the tracing procedure. A FORTRAN implementation of the algorithm is available from the authors at <http://www.personeel.unimaas.nl/r.peeters>.

Another equilibrium computation and selection approach based on a process of behavioral adjustment uses the quantal response equilibrium of McKelvey and Palfrey [19]. In a quantal response equilibrium, the payoffs to each strategy are perturbed by an additive, independent stochastic shock. Under specified conditions, as the variance of this random shock goes to zero, the set of quantal response equilibria converge to a subset of the set of Nash equilibria. Turocy [20,21] demonstrated the method of using the results of McKelvey and Palfrey for the case when the shock follows the extreme value distribution to compute an arbitrarily good approximation of a Nash equilibrium by following a differentiable path of quantal response equilibria. This path can be interpreted as having the same conceptual structure of introspection and adjustment as the tracing procedure, but, since it uses a different dynamical system, it does not necessarily result in the same equilibrium as selected by the tracing procedure. This is implemented in Gambit as the gambit-logit command-line tool. This approach has an independent interest in laboratory experiments in game theory, where the quantal response equilibrium is used to organize the behavior of subjects playing games in controlled experiments (see, e.g., Goeree and Holt [22]).

Individually, none of the preceding three methods (global Newton, tracing procedure, quantal response equilibria) are guaranteed to be able to find all equilibria, even in games where the equilibria are isolated points. However, taken together, they are still useful elements of a toolkit for analyzing strategic games. Since they are approximation-based methods, the intermediate output they generate has a meaningful game-theoretic interpretation either as the exact equilibrium of an approximation to the original game or an approximate equilibrium to the exact original game. Also, often they find different equilibria when applied to a game.

Therefore, some questions, such as whether a game has a unique equilibrium, may in practice be answered most easily by applying a combination of these methods, rather than setting up an exhaustive search involving the solution to many systems of polynomial equations.

A final word of caution is in order when working with games with more than two players. Unlike two-player games, the set of Nash equilibria of a game with more than two players need not be expressible as the union of a finite number of convex sets. For a simple three-player example that illustrates this possibility, see Nau *et al.* [23]. Since, as noted before, many games that arise in practical applications may have positive-dimensional sets of equilibria, this possibility should be kept in mind. As of this writing, there is no tool that will reliably find and report the existence of such positive-dimensional sets. There is some support in the Bertini package for exploring positive-dimensional solution sets that could be brought to bear on the problem. In many cases, the existing PHCpack or Bertini implementations may fail to report any equilibria on a support, when in fact a positive-dimensional set of equilibria exists there. The global Newton, tracing procedure, and quantal response methods, if they find equilibria in such a component, will generally report only individual points from the component, and give no indication of the existence of equilibria nearby.

SUMMARY AND OUTLOOK

There exist a good set of tools for the practitioner to create, manipulate, and solve non-cooperative strategic form games. Advances in algorithm development, particularly in the solution of systems of polynomial equations, and the steady decrease in the price of computational power, have combined to significantly expand the size of games that can be analyzed on commodity hardware. For small applications, these tools may be able to provide essentially off-the-shelf, black-box solutions, particularly in the case of games with only two players.

In aiming to be a field guide for computing equilibria, this article omits many details of

the algorithms mentioned, as well as many other approaches to computing Nash equilibria. The survey of McKelvey and McLennan [24] is a good, if becoming dated, deeper introduction to the topic. A good resource for updates is the January 2010 issue of the journal *Economic Theory*, which was devoted entirely to the computation of Nash equilibria in finite games, and included the surveys of Avis *et al.* [10] and Herings and Peeters [13] mentioned earlier.

In view of the complexity results cited, no amount of algorithmic cleverness or hardware capacity will make the problem of computing the full set of equilibria of a strategic game fully tractable. Some current directions of research in this area involve heuristics which improve the average-time performance in, for instance, finding one equilibrium in particular classes of games; some progress in this direction has been reported by Porter *et al.* [25]. Another direction in the analysis of games is being advanced by behavioral game theory. If a Nash equilibrium is difficult to find, as the results on computational complexity of finding equilibria indicate, then it seems unsatisfactory to expect players to arrive at a Nash equilibrium in practice. Instead, predictions based on simpler heuristics such as level- k reasoning (Stahl [26]) or cognitive hierarchy models (Camerer *et al.* [27]) have been shown to organize how subjects in controlled laboratory experiments play games better than Nash equilibrium, and as such might be superior models for how players make strategic decisions in novel situations.

Influence diagrams [1] are popular graphical models in decision analysis for representing, solving, and analyzing a single decision maker's decision situation. Many of the important relationships among uncertainties, decisions, and values can be captured in the structure of these models, explicitly revealing irrelevance and the timing of observations. The phrase "solving influence diagrams" refers to computing the optimal strategy and the value at the optimal strategy, based on the norms of decision analysis. In this article, we highlight some of the most popular exact methods for solving influence diagrams.

Influence diagrams were initially conceived as tools primarily to be used in the formulation stage to assess the beliefs of a decision maker. However, research has shown that they are also efficient computational tools for the evaluation stage, and not merely graphical depictions for communicating ideas between the decision maker and the analyst [2,3]. There have been many developments in solution and analysis since then [4–11,12,13].

Methods for the solution of decision analysis problems have mainly been based on three graphical representations: decision trees, influence diagrams, and cluster trees. Decision trees are commonly taught in a first course in decision analysis. They are able to capture the asymmetries in real-world decision problems, and are easy to understand since they capture the informational order of variables in decision situations. On the other

hand, influence diagrams capture the conditional independencies in the model and are able to represent the model as conveniently assessed by the decision maker. Cluster trees are a solution representation derived from influence diagrams and will be presented in the section titled "Solving Influence Diagrams: Cluster Trees." In the next section we introduce the terminology and notation for influence diagrams used in this article.

INFLUENCE DIAGRAMS

Node and Arc Semantics

To describe a decision situation, a decision maker defines a number of *variables*. When a variable is *uncertain*, it represents a feature in the decision situation that the decision maker has no control over, and its possibilities are the *states* of the uncertainty. When a variable is a *decision*, the decision maker can choose to pursue any of its *alternatives*. In this article, we will deal with decision situations where there are a finite number of states or alternatives. We allow uncertainties to be *observed* to take specific states for certain and these observations are known as *evidence*.

An influence diagram is a directed graphical model for reasoning under uncertainty with nodes corresponding to the variables. Variables are denoted by upper case letters (X) and their states by lower case letters (x). A bold faced letter indicates a set of variables ($\mathbf{X}$). We will refer interchangeably to a node in the diagram and the corresponding variable. If there is an arc directed from node X to node Y , X is known as a *parent* of Y , and Y is a *child* of X . A node along with its parents forms the *family* for that node. The parents for node X are denoted $\mathbf{Pa}(X)$, and the family is $X\mathbf{Pa}(X)$. If there is a directed path from node X to node Y , we say that X is an *ancestor* of Y , and that Y is a *descendent* of X . Influence diagrams are *acyclic* graphs, meaning that there is no node X in the graph that is its own ancestor.

Influence diagrams have three kinds of nodes, decision, *uncertain (or chance)*, and *value* nodes, which together represent choices, beliefs, and preferences. Decision nodes are drawn as rectangles, uncertain nodes as ovals, and value nodes as rounded rectangles (or polygons). Decision nodes correspond to decision variables that are under the control of the decision maker and uncertain and value nodes correspond to variables that are not.

The semantics of an arc in an influence diagram depends on the type of node it is directed toward. Arcs directed into an uncertain or value node X are *conditional arcs*, and the distribution assessed for X is conditioned on its parents, $P\{X|\mathbf{Pa}(X)\}$. For value variables, we assume that this distribution can be represented as a deterministic function of the parent variables. *Informational arcs* directed toward decision nodes indicate those variables that will be observed before the decision is made. An influence diagram is *completely specified* if states (or alternatives) are assigned for each node, as well as conditional probability distributions for all uncertain nodes.

We will demonstrate some solution algorithms with the help of an influence diagram example from Jensen *et al.* [7], shown in Fig. 1. This influence diagram has four decision nodes $D1$ through $D4$, four value nodes $V1$ through $V4$, and twelve uncertain nodes A through L .

Maximizing Expected Utility

The criterion for decision making is represented by the value nodes. In this article, we assume that there may be multiple value nodes in the influence diagram, which are summed to obtain the total value. Influence diagrams with multiple additive or multiplicative value nodes were introduced and solved by Tatman and Shachter [14]. We assume that the value nodes characterize the value of the attributes in terms of a single numeraire, which we assume is dollars, and that there is a von Neumann–Morgenstern utility function $u(\cdot)$ applied to their total [15]. The utility function $u(\cdot)$ is typically assumed to be strictly increasing and continuously differentiable. The *certain equivalent* (CE) of an

uncertain $\mathbf{V}$ represents the certain payment that the decision maker finds indifferent to $\mathbf{V}$, and is given by $u^{-1}(E[u(\sum_{V \in \mathbf{V}} V)])$. The most common utility functions are *linear*, $u(v) = av + b$, and *exponential* functions of the sum of the values, $u(v) = -ae^{-v/\rho} + b$, where $a > 0$ and $\rho > 0$, both of which allow us to express the *value of information* [16,17] exactly in closed form. For simplicity, in this article we will assume a linear utility function. Note that the linear utility function corresponds to a risk-neutral decision maker, and in this situation the certain equivalent is equal to the maximum expected total value.

Thus the general problem we describe is to determine the decisions $\mathbf{D}$ that maximize the expected sum of values when the variables $\mathbf{E}$ have already been observed and the parents of each decision D are observed before it is made. In other words, the goal is to find the *optimal strategy*, given that evidence $\mathbf{E} = \mathbf{e}$ has been observed. Therefore, the solution of an influence diagram should reveal the optimal strategy and the certain equivalent of the decision situation, informing the decision maker about what to do in his/her decision situation, and what the decision situation is worth to him/her.

Other Standard Assumptions and Requirements

It is inconsistent to make observations that tell us anything about the decisions we are

Figure 1. Influence diagram example from Jensen *et al.* [7].

Figure 2. Decision windows for the influence diagram from Fig. 1.

yet to make, so we require that evidence variables **E** not be *responsive* in any way to **D** [18]. This is enforced by not allowing the nodes in **E** to be descendants of the nodes in **D**.

We also require that there be a total ordering of the decisions. In the case of the diagram in Fig. 1, the decisions are made in the order $D1, D2, D3$, and $D4$. We assume *no forgetting*, that all earlier observations and decisions are observed before any later decisions are made. No forgetting is a standard assumption for influence diagrams, and the no forgetting arcs are usually not drawn in the diagram when they can be inferred implicitly. For example, since there is a directed path from $D1$ to $D2$, there does not need to be an explicit arc from $D1$ to $D2$, but there should be directed arcs from $D2$ to $D3$ and $D3$ to $D4$. That way, it is clear that F is observed before $D3$.

No forgetting can also be understood using the notion of *decision windows* [19]. The total ordering of the decisions in the no forgetting ordering imposes a partial order on the other variables. Figure 2 shows decision windows for our influence diagram example, which indicate what variables are known at the time of each decision. The windows are one-way in the sense that future decisions can observe anything from earlier windows but nothing from the future. From Fig. 2, note that B is observed before $D1$ and therefore is known at the time all decisions are made. Any evidence would also be in this window. Uncertainties A, C, D, H, I, J, K, L are not known at the time of any decision; hence they are placed in the decision window after the last decision $D4$.

We assume that the influence diagram is a *single component*, that is, there is at least one path between any two nodes if we ignore

the direction of the arcs. Otherwise, we can solve each component independently. We also assume that there are no nodes which can be simply removed. For example, some non-responsive variables might become relevant if observed.

Requisite Observations

We make a quick note about *requisite* observations [5,20,21]. Evaluating an influence diagram entails finding the optimal alternative for every decision under the given observations available for the decision. However, based on the structure of the graph, only some of the observations are needed for a particular decision and there can be significant efficiency gains by recognizing which of the available observations are *requisite* for each of the decisions. The requisite observations for each decision can be computed, in reverse order, by considering which observations are relevant to the value descendants of the decision [20–22].

Therefore, a preprocessing step can be carried out on the influence diagram under consideration. In this preprocessing step, if an observation is not requisite for a decision, the arc from that observation into the decision is removed. Figure 3 presents the influence diagram example where preprocessing has been carried out and shows the requisite observations for every decision. Note that, although Fig. 3 has more arcs than Fig. 1, it actually reflects a significant reduction in graph complexity since the no forgetting arcs were hidden in Fig. 1. For instance, B is available at the time of all decisions, but it is not requisite for any decision other than $D1$, hence there are no arcs from B to $D2, D3$ or $D4$ in Fig. 3.

Figure 3. Requisite observations for the influence diagram from Fig. 1.

SOLVING INFLUENCE DIAGRAMS: DECISION TREES

One way to solve an influence diagram is to convert it into a decision tree [1] and then solve the tree. To be able to do this, the influence diagram must be a *decision tree network*, where all the ancestors of any decision node are parents of that node. Equivalently, if we call an arc between uncertain nodes *nonsequential* if the parent is in a later decision window than the child, a decision tree network is an influence diagram without nonsequential arcs.

Any influence diagram satisfying our assumptions can be transformed into a decision tree network through a sequence of *arc reversals* [19]. Arc reversal applies Bayes' rule to reverse the topological order of uncertain nodes [2,3]. An arc from uncertain node X to uncertain node Y with parent sets $\mathbf{A}, \mathbf{B}$, and $\mathbf{C}$ can be reversed, as shown in Fig. 5a, unless there is another directed path from X to Y ; if there were, then reversing the arc would create a directed cycle. When the arc (X, Y) can be reversed, the joint distribution of X, Y conditioned on $\mathbf{A}, \mathbf{B}, \mathbf{C}$ can be factored two ways:

$$\begin{aligned} P\{X, Y | \mathbf{A}, \mathbf{B}, \mathbf{C}\} &= P\{X | \mathbf{A}, \mathbf{B}\} P\{Y | X, \mathbf{B}, \mathbf{C}\} \\ &= P\{X | Y, \mathbf{A}, \mathbf{B}, \mathbf{C}\} P\{Y | \mathbf{A}, \mathbf{B}, \mathbf{C}\}. \end{aligned}$$

The new distribution for Y given $\mathbf{A}, \mathbf{B}, \mathbf{C}$ is obtained by marginalizing X from the joint

$$\begin{aligned} P\{Y | \mathbf{A}, \mathbf{B}, \mathbf{C}\} &= \sum_x P\{X = x, Y | \mathbf{A}, \mathbf{B}, \mathbf{C}\} \\ &= \sum_x P\{X = x | \mathbf{A}, \mathbf{B}\} P\{Y | X = x, \mathbf{B}, \mathbf{C}\}, \end{aligned}$$

and it is used to obtain the new distribution for X given $Y, \mathbf{A}, \mathbf{B}, \mathbf{C}$:

$$\begin{aligned} P\{X | Y, \mathbf{A}, \mathbf{B}, \mathbf{C}\} &= \frac{P\{X, Y | \mathbf{A}, \mathbf{B}, \mathbf{C}\}}{P\{Y | \mathbf{A}, \mathbf{B}, \mathbf{C}\}} \\ &= \frac{P\{X | \mathbf{A}, \mathbf{B}\} P\{Y | X, \mathbf{B}, \mathbf{C}\}}{P\{Y | \mathbf{A}, \mathbf{B}, \mathbf{C}\}}. \end{aligned}$$

The influence diagram shown in Fig. 1 is not a decision tree network, because the arcs (C, E) , (D, E) , and (D, F) are nonsequential. We can obtain a decision tree network by reversing those arcs. Note that in the process nonsequential arcs would be created from A to E and F that would also need to be reversed. We simplify matters by reversing (A, C) before reversing the nonsequential arcs. Figure 4 presents the decision tree network for the example, after the four arc reversals. Note that in Fig. 1, D is an ancestor but not a parent of decisions nodes $D2$,

Figure 4. Decision tree network for the influence diagram from Fig. 1.

$D3$, and $D4$, while in Fig. 4, it is no longer an ancestor of any decision nodes.

Decision trees are easy to understand but they become intractable for decision situations involving a large number of variables since they are exponential in the number of nodes. Decision trees do have some advantage in that they may be able to better represent asymmetric decision situations such as the used car buyer problem [23]. We briefly discuss asymmetry later in the article. Larger decision situations may be more amenable for representation and solution through other means. In the following sections, we review techniques that are able to exploit the conditional independence of the influence diagram, and therefore reduce the complexity of the solution.

SOLVING INFLUENCE DIAGRAMS: MODIFICATIONS TO THE DIAGRAM

A *variable elimination algorithm* directly evaluates the original influence diagram through a sequence of node elimination steps [2,3,14,24]. The algorithm iteratively removes nodes from the diagram until all that remains is a value node and any evidence nodes, representing the optimal value of the influence diagram and the observations already made. The optimal strategy is determined in terms of an optimal policy for each decision before that decision is eliminated.

The algorithm recognizes a variety of conditions under which nodes can be eliminated, and at least one node can be removed in any proper influence diagram until all that remains are value and evidence nodes. For example, *barren nodes* are decision or unobserved uncertain nodes that have no children. These variables have no effect upon the value and can be simply removed from the diagram. These might be present in the original diagram or created in the process of variable elimination.

There are four other graphical transformations needed: arc reversal between uncertain nodes discussed in the previous section, and a removal operation for each type of node: decision, uncertain, and value.

When an uncertain node has only one child, and that child is a value node, *uncertain node removal* eliminates the node from diagram by taking expectation, and the value node inherits its parents as shown in Fig. 5b,

$$\begin{aligned} E[V|\mathbf{A}, \mathbf{B}, \mathbf{C}] \\ = \sum_x P[X = x|\mathbf{A}, \mathbf{B}] E[V|X = x, \mathbf{B}, \mathbf{C}]. \end{aligned}$$

When a decision node has only one child, that child is a value node, and all other parents of the value node are also parents of the decision node, *optimal policy determination* replaces the decision node with a (deterministic) uncertain one, representing the optimal policy for each possible combination of the other parents of the value node as shown in Fig. 5c,

$$E[V|\mathbf{B} = \mathbf{b}] = \max_d E[V|D = d, \mathbf{B} = \mathbf{b}],$$

for all possible $\mathbf{b}$. That policy node can then be removed, but the optimal policy should be saved.

When there are multiple value nodes, *value node removal* replaces two value nodes by one value node equal to their sum with the union of their parents, as shown in Fig. 5d,

$$E[V_1 + V_2|\mathbf{A}, \mathbf{B}, \mathbf{C}] = E[V_1|\mathbf{A}, \mathbf{B}] + E[V_2|\mathbf{B}, \mathbf{C}].$$

To exploit the decomposition of the value, this operation should be delayed as long as possible, ideally until the parents of one of the value nodes are all parents of the other, or when both value nodes are descendants of the latest decision.

Given these operations, an influence diagram with no directed cycles and ordered decisions with no forgetting can be solved by the following algorithm [3,14]. First, if any of the value nodes has a child, turn it into an uncertain node and give it a value child equal to itself.

Repeat, until all that remains is a single value node and the evidence nodes:

1. If there is a barren node, remove it.
2. Otherwise, if the latest decision node has exactly one child, a value node,

Figure 5. The four graphical transformations to the influence diagram.

and all of the other parents of the value are observed before the decision, then determine its optimal policy and remove it.

3. Otherwise, if there is an uncertain node that is not observed before the latest decision and has [at most] one value child, then remove it after reversing any arcs to its nonvalue children in graph order.
4. Otherwise, a value node needs to be removed, preferably a descendant of the latest decision or when its parents are all parents of another value node.

Let us demonstrate the algorithm with the help of value reduction steps shown in Fig. 6. Figure 3 presents the original influence diagram with the requisite observations

for all decisions. Figure 6a shows the diagram after the removal of five unobserved uncertain nodes, L , I , J , K , and H . The optimal policy for $D4$ can now be determined, and Fig. 6b shows the diagram after the decision node $D4$ has been removed and the value nodes $V3$ and $V4$ have been summed so that the policy for $D3$ can be determined. Uncertain node G and decision node $D3$ have been removed in Fig. 6c. Decision node $D2$ and uncertain node F have been removed in Fig. 6d. Uncertain nodes E , A , and C have been removed in Fig. 6e. Value nodes $V2$ and $V3 + V4$ have been summed in Fig. 6f so that uncertain node D can be removed in Fig. 6g. The two value nodes are summed in Fig. 6h so that decision node $D1$ can be removed in Fig. 6i. Finally, uncertain node B is removed in Fig. 6j, so that only the total value remains.

Figure 6. Node reduction steps for the influence diagram from Fig. 1.

SOLVING INFLUENCE DIAGRAMS: CLUSTER TREES

Much of the popularity of belief networks arises from the improvement in computational power through the development of

efficient algorithms, many of which use graphical structures called *chordal graphs* and *cluster trees*, abstracted from the original diagram [25–27,13]. Several modified versions of these algorithms have been able to tackle the problem of solving influence

Figure 7. Requisite observations and moral edges for the influence diagram from Fig. 1.

Figure 8. Undirected graph for the moralized diagram from Fig. 7.

diagrams [6–8,21]. Much has been written about the construction of chordal graphs and cluster trees, and we will present a simplified version, enough to show how they can be used to solve influence diagrams.

We start with a variable elimination ordering similar to the one we presented in the previous section. For the diagrams in Fig. 6, the order of uncertain and decision node removal was $L, I, J, K, H, D4, D3, G, D2, F, E, A, C, D, D1$, and B . We treat all of the value nodes as if they were eliminated before any other variables.

The first step is to ensure that each node's family will be together to represent its conditional distribution. We add *moralizing edges*, undirected edges between the parents of a node, if there is not already an arc between them. Starting with the requisite observations in Fig. 3, we add moralizing edges to obtain the diagram shown in Fig. 7. For example, A and B are parents of C with no arc between them so an undirected moralizing edge is added between them.

The next step is to create an undirected version of the graph shown in Fig. 7 as shown in Fig. 8. We would ideally like this graph to be *chordal* or *triangulated*, where any undirected circuit of length four or more has a chord, as this one does, but we will add these extra edges in the next step, if necessary.

Now we construct a directed version again, using the variable elimination order. Arcs are directed toward the earlier variables to be eliminated from the later ones, as shown in Fig. 9. This graph must also satisfy an important condition to be a *directed chordal graph*: there must be a directed arc between any two nodes with a common child [13]. Unlike the moralizing edges, these new arcs can themselves create the need for additional arcs. When we add them, we use the elimination order to determine the direction of the arcs. In this example, because the graph in Fig. 8 is chordal and this elimination order is “perfect,” we have no new arcs to add. However, if C were eliminated before A , then there would be an arc from A to C and we would have needed to add an arc from D to A since both of them would be parents of C . The best elimination order is one that requires no extra arcs in this diagram.

We are now prepared to construct a *rooted cluster tree* [6] (also called a *strong junction tree* [7]), a directed tree with each node corresponding to a *cluster* or set of variables, and satisfying four important properties: (i) there is one root cluster with no child clusters, and all other clusters have exactly one child; (ii) there are arcs in the directed chordal graph between all of the variables in each cluster; (iii) if the same variable appears in two clusters, it appears in every cluster in between them in the tree; and (iv)

Figure 9. Directed chordal graph for the influence diagram from Fig. 1.

Figure 10. Rooted cluster tree for the influence diagram from Fig. 1.

if one cluster follows another in the tree, then the variables that are only in the parent cluster will be eliminated before any of the variables in the child cluster.

There can be many different rooted cluster trees for the influence diagram shown in Fig. 1, depending on the elimination order, and even with the same elimination order, but here is an algorithm to construct the rooted cluster tree shown in Fig. 10, from a directed chordal graph such as Fig. 9.

1. Select the variable having no parents, X , mark all other nonvalue variables as *unselected*, set the *current* cluster to be $\{X\}$, and make it the root cluster.
2. While there is at least one unselected variable X , with all of its parents comprising the current cluster, select the latest such X in the elimination order and add it to the current cluster.
3. If there are no more unselected variables, we are done. Otherwise, select the unselected variable X latest in the elimination order, creating a new current cluster with its family, $X\text{Pa}(X)$. Make this current cluster parent to one of the clusters containing all of X 's parents; we suggest that the child cluster should be chosen as close to the root cluster as possible. Now go to step 2.

In our example, variables B , $D1$, and D would be selected to form the root cluster. Variable C is selected next and the cluster $\{B, C, D\}$ is created as a parent of cluster $\{B, D1, D\}$. Variable A is selected next, and the cluster $\{A, B, C\}$ is created as a parent of $\{B, C, D\}$. This proceeds until all of the variables, except the value variables, have been included in clusters, and those clusters have been added to the tree. Note that for our purposes, we do not need to have the value variables in clusters.

The first step in solving the influence diagram with the cluster tree is to associate each uncertain variable X with a cluster in the cluster tree that contains the family of X , $X\text{Pa}(X)$. (For value variables, the family does not need to include the value variable itself, just its parents.) The addition of moralizing edges guarantees that there will be at least one such cluster for each uncertain variable. In the cluster tree shown in Fig. 10, the variable B could be associated with any of the three clusters containing B , but C must be associated with A, B, C because that is the only cluster containing its family in Fig. 1.

For each cluster, we compute a *utility potential* as the product of all of the conditional probabilities (and evidence likelihoods) of the uncertain variables associated with that cluster. For example, if B is associated with cluster B, C, D , then its

utility potential would be $P\{B\}$; otherwise, if no variables were associated with the cluster its utility potential would be 1. Cluster H, J, K is associated with variables, J, K , and $V3$, so its utility potential would be $P\{J|H, K\}P\{K|H\}E[V3|J, K]$.

For each cluster, we also compute a *probability potential*, similar to the utility potential, except that it does not include expectation factors for value variables. For example, the probability potential for B, C, D would be the same as its utility potential, but the probability potential for H, J, K would be $P\{J|H, K\}P\{K|H\}$.

We then visit each cluster in graph order. We multiply the cluster potentials by any corresponding potentials we received from parent clusters. We then eliminate, in order, those variables not present in its child cluster. For uncertain variables, we sum over all states of the variable in both potentials. For decision variables, we need to maximize over the utility potential for each state of the requisite variables, all of which will be in that cluster, and select the corresponding element from the probability potential. (For value variables, there is no need to do anything.) The resulting potentials should be a function of variables in the child cluster and they should be passed along to it.

At the end, in the root cluster, we have a single number left in each potential. The probability potential equals the probability of the evidence, and the utility potential divided by the probability potential equals the maximal expected value. The optimal strategy is represented by the maximization choices we made for the decision variables.

For example, in cluster H, J, K we sum the potentials over the states of J and pass along the new potentials, as a function of H, K to cluster $D3, H, K$. We multiply that cluster's own potentials, $P\{K|D3, H\}E[V4|D3]$, by the passed potential, sum over the states of K , and pass the resulting potential as a function of $D3, H$ to cluster $F, D3, H$. We multiply that cluster's own potential, $P\{H|F\}$, by the passed potential, sum over the states of H , and maximize over $D3$ given F , saving the optimal choices. We pass the resulting potential as a function of F to cluster D, F . We continue processing each cluster this way until the root

cluster's potentials are reduced to a single number each.

The cluster tree method uses the conditional independence in the diagram and organizes the computations so that summation and maximization operations occur in the appropriate order. We provided a brief overview of solving influence diagrams with cluster trees, leaving out many of the details. Shachter and Peot [6], Jensen *et al.* [7], Shachter [21], and Jensen and Nielsen [28] are some references for further reading on cluster tree construction and evaluation with message passing.

OTHER RELATED TOPICS

The literature on influence diagrams is vast and varied; here we provide a quick overview of other related topics.

Asymmetry

The methods we have described for solving influence diagrams exploit the *global structure* of the influence diagram, that is, the topology of the graph, and in particular through conditional independence and separable values. The complexity of the influence diagram at the level of global structure is studied in terms of the number of nodes and the *treewidth*, which is a measure of the connectivity of the network. On the other hand, *local structure* refers to the specific numbers used for building the graphical model. Here we discuss the issue of local structure in influence diagrams.

Real-world decision situations often exhibit a significant amount of *asymmetry*, that is, decision situations where some possible combinations of variables have no meaning. In an influence diagram representation, this typically means that the full rectangular table does not need to be evaluated. Asymmetry in the decision situation is represented through the numbers in the model, and mainly in the form of *determinism*, or the presence of zeros in conditional probability distributions, and *context specific independence* [29], which refers to independence between variables given a particular instantiation of some

other variables. In most real-world decision situations, there is a tremendous opportunity to also exploit the specific numbers in the model so that evaluation and analysis can be made even more efficient. Previous research has shown the potential benefits from tapping local structure for improving evaluation efficiency [30,31].

Influence diagrams face some difficulty in representing asymmetric decision situations. Some of the shortcomings of influence diagrams for representing asymmetric situations are documented in Smith *et al.* [31], Bielza and Shenoy [32], and Shenoy [33]. Several researchers have worked on trying to extend and augment the influence diagram representation to capture asymmetry directly, see for instance Covaliu and Oliver [34], Shenoy [35], and Jensen *et al.* [36]. Another direction of research has been to focus on identifying ways to exploit the asymmetry while solving the influence diagram. This has been actively pursued in the belief network literature, with the help of graphical representations such as arithmetic circuits [37,38]. Decision circuits have been developed to perform efficient evaluation of influence diagrams [9,13], building on the advances in arithmetic circuits for belief network inference. The benefit of the decision circuit framework is that compact circuits are compiled in an offline phase so that subsequent on-line operations for evaluation and analysis can be more efficient. This can be particularly useful in situations for real-time decision making and in decision systems [39], that is, for decision situations under uncertainty that recur frequently and involve considerable automation.

Other Related Graphical Models

In the previous section, we mentioned a few graphical models for specifically dealing with the issue of asymmetry. There are various other graphical models closely related to the influence diagram literature.

There are other graphical models for representing and solving decision problems, such as game trees [40] and valuation networks [41]. The fusion algorithm for solving valuation networks is closely related to the cluster tree methods described here.

There have also been several extensions to influence diagrams that relax some of the assumptions, such as limited memory influence diagrams (LIMIDs) [42], unconstrained influence diagrams [43], and so on. Many of these graphical models are harder to solve than standard influence diagrams and, like the graphical models for representing asymmetry, are rather complex. There is also a considerable amount of literature on influence diagrams with continuous uncertain variables, starting with Shachter and Kenley [44]. Another direction of research has been on extending influence diagrams to problems with multiple decision makers [42,45,46].

Sensitivity Analysis and Value of Information

The phrase *sensitivity analysis* refers, in general, to understanding how the output for a system varies as a result of changes in the system's inputs. For influence diagrams, one may be concerned about how the optimal solution and the value change with respect to a change in the parameters, that is, the probabilities and the utilities, or a change in the informational assumptions of the problem. Sensitivity analysis has been an essential aspect of decision analysis throughout the field's development. Sensitivity analysis aids in identifying the model's critical elements, forming the basis for iterative refinement of the model, and can also be used after the analysis for defending a particular strategy to the decision maker [47].

Sensitivity analysis is an essential technique to support influence diagram modeling and it provides valuable insight about the critical assessments. Sensitivity analysis for influence diagrams has been studied in Nielsen and Jensen [10] and Bhattacharya and Shachter [11,12]. Decision circuits are particularly suitable for performing sensitivity analysis on influence diagrams since partial derivatives are easy to compute with compiled circuits, and therefore analysis on the model can be performed conveniently within this framework.

One of the most powerful sensitivity analysis techniques of decision analysis is the computation of *value of information* (or clairvoyance), which is the difference in value obtained by changing the decisions by

which some of the uncertainties are observed [16,17]. The value of information for a particular uncertainty specifies the maximum that the decision maker should be willing to pay to observe the uncertainty before making a particular decision. Value of information can be computed on the cluster tree used to solve the original problem [21] or in other ways [11,48].

SOLVING STOCHASTIC PROGRAMS

GÜZİN BAYRAKSAN
University of Arizona,
Department of Systems and
Industrial Engineering,
Tucson, Arizona

Stochastic programming extends deterministic optimization by including random parameters and probabilistic statements in model formulation. It has been successfully applied for decision making under uncertainty in diverse fields such as finance, energy, manufacturing, transportation, supply chain, and environmental management among others [1]. A general stochastic program can be formulated as follows:

$$\min_{x \in X} \left\{ \mathbb{E}f_0(x, \tilde{\xi}) : \mathbb{E}f_k(x, \tilde{\xi}) \leq 0, k = 1, 2, \dots, K \right\}, \quad (\text{SP})$$

where f_k , $k = 0, 1, \dots, K$ are extended real-valued functions with inputs being the decision vector x and a realization of the random vector $\tilde{\xi}$. $X \subset \mathbb{R}^{d_x}$ represents the set of deterministic constraints that x must satisfy, and $\Xi \subset \mathbb{R}^{d_\xi}$ denotes the support of $\tilde{\xi}$, where d_x and d_ξ are the dimensions of the vectors x and $\tilde{\xi}$, respectively. We assume that $\tilde{\xi}$ has distribution, $\mathbb{P}$, that is independent of x , and the expectations in (SP), taken with respect to the distribution of $\tilde{\xi}$, are well-defined and finite for all $x \in X$.

A wide variety of problems can be cast as (SP) depending on K , X , and f_k , $k = 0, 1, 2, \dots, K$. For example, in a two-stage stochastic linear program with recourse, $K = 0$, $X = \{Ax = b, x \geq 0\}$, and $f_0(x, \tilde{\xi}) = cx + h(x, \tilde{\xi})$, where $h(x, \tilde{\xi})$ is the optimal value of the linear program

$$\begin{aligned} h(x, \tilde{\xi}) &= \min_y \tilde{q}y \\ \text{s.t.} \quad &\tilde{W}y = \tilde{r} - \tilde{T}x, \quad y \geq 0. \end{aligned}$$

Here, $\tilde{\xi}$ is a random vector that is comprised of random elements of $\tilde{q}$, $\tilde{W}$, $\tilde{R}$, and

$\tilde{T}$. Stochastic programs with recourse model time-staged decisions under uncertainty that are common in practice. For instance, decisions on where to locate factories and warehouses must be made without a full knowledge of the uncertainties like demands. When uncertainties become known, recourse decisions such as minimum cost transportation of goods to demand points, and overtime and subcontracting to meet excess demand are made. These recourse decisions are captured in the second stage of the above problem. In contrast, in a stochastic program with a single probabilistic constraint, $K = 1$, $f_0(x, \tilde{\xi}) = cx$, and

$$f_1(x, \tilde{\xi}) = \mathbb{I}(\tilde{A}'x \geq \tilde{b}') - \alpha,$$

where $\mathbb{I}(\cdot)$ denotes the indicator function that takes value 1 if its argument is true and zero otherwise, and $\alpha \in (0, 1)$ is a desired probability level. In this case, $\tilde{\xi}$ is comprised of random elements of $\tilde{A}'$ and $\tilde{b}'$. Here, a single stage decision is made by taking into account the probability of an “event” of interest. For instance, this event can be “not meeting demand” and its probability can be limited to a desired level.

Stochastic programs constitute one of the hardest classes of optimization problems to solve. A major challenge in algorithmic design for stochastic programs stems from the need to calculate multidimensional expectations that appear in (SP). When d_ξ , the dimension of $\tilde{\xi}$, is moderate-to-high and $\tilde{\xi}$ is continuous or has a large number of realizations, calculating $\mathbb{E}f_k(x, \tilde{\xi})$, $k = 0, 1, \dots, K$ might not be possible even for a fixed x . Algorithms typically require these function evaluations, along with other more complicated function evaluations such as subgradients of these expectations, in an iterative fashion for many different x . Even if the expectations can be calculated for a fixed x , optimization over the set of feasible solutions can be quite challenging. For example, two-stage stochastic integer programs with integer second stage can

result in a discontinuous and nonconvex objective function in x . Many stochastic programs with probabilistic constraints have nonconvex feasible regions. Therefore, a second major difficulty in algorithm design for certain classes of stochastic programs is having to deal with a challenging nonconvex optimization problem.

Despite the aforementioned difficulties, there has been a steady progress toward developing solution methods for stochastic programs. Algorithm design for stochastic programs depends heavily on the class of problem being addressed and relies on exploiting the special structures of that class. That said, certain algorithmic ideas, such as decomposition, are repeatedly used in solving stochastic programs. Below, we review some of these commonly used algorithmic ideas. To illustrate the concepts, we use two-stage stochastic linear programs as an example and point out references for other classes of problems. We note that our treatment is brief in nature and serves as an introduction; as such, we refer the interested readers for further reading in the section titled “Concluding Remarks”. We assume a basic familiarity with optimization. Before we begin a more detailed look into these algorithmic ideas, we first give a broad overview.

Solution methods for stochastic programs can be classified into two categories: (i) exact and (ii) approximate solution methods. Exact solution methods are typically used when the number of realizations of $\tilde{\xi}$ is small-to-moderate. They also allow solution of approximations of stochastic programs. For example, Monte Carlo sampling-based approximations that use a sample size of n turn (SP) into a problem with a discrete distribution that has at most n realizations. Then, the resulting approximate problem can be solved via one of the exact solution methods. Given that it is not possible to solve many stochastic programs exactly, approximate solution methods are paramount in stochastic programming. The main idea here is to approximate the stochastic program with a much smaller, computationally tractable one. A desirable property of these approximations and the solutions obtained

via these approximations is that they converge to the true problem and its solution set in some sense. We now examine the two categories in more detail.

EXACT SOLUTION METHODS

An underlying theme of exact solution methods for stochastic programs is the exploitation of the special structures found in many stochastic programs to achieve tractability. For example, consider a two-stage stochastic linear program with recourse described above and assume $\tilde{\xi}$ has a finite number of realizations $\{\xi^1, \xi^2, \dots, \xi^S\}$, called *scenarios*, with respective probabilities $p^1, p^2, \dots, p^S$. Then, the two-stage stochastic linear program with recourse can be written in extensive form as a large scale linear program

$$\begin{aligned} \min_{x, y^1, \dots, y^S} \quad & cx + \sum_{s=1}^S p^s q^s y^s \\ \text{s.t.} \quad & Ax = b, \\ & T^s x + W^s y^s = r^s, \quad s = 1, 2, \dots, S, \\ & x \geq 0, \quad y^s \geq 0, \quad s = 1, 2, \dots, S. \end{aligned} \tag{1}$$

Note that in (SP) optimization is with respect to x ; while in the extensive form in Equation (1), optimization is with respect to x and $y^1, y^2, \dots, y^S$. Decisions x , called the *first stage decisions*, do not depend on a particular scenario s and must be made before knowing the realization of the random parameters. In contrast, decisions $y^1, y^2, \dots, y^S$, called the *second stage decisions*, depend on a particular scenario s . The constraint matrix of this linear program has a special structure, called the *block structure* [2, Chapter 5], which can be exploited to design efficient algorithms. A class of exact solution methods modifies well-known optimization algorithms to be efficiently used for stochastic programs by exploiting this structure. These include simplex-based algorithms [3] and interior point method implementations specific to stochastic programs [4–7].

Decomposition is a commonly used technique in stochastic programming as many stochastic programs are decomposable by

scenario and/or by stage. It is a classic “divide and conquer” technique that replaces a large scale, difficult problem with a number of smaller, tractable problems. Solving these smaller problems is more efficient than solving one large scale problem. Decomposition-based algorithms have been successfully used to solve two and multistage stochastic programs—some with risk-averse objectives [8,9]—as well as aiding efficient solution of other classes of (SP) such as stochastic programs with probabilistic constraints [10]. In the rest of this section, we discuss two common decomposition techniques in detail.

Primal Decomposition and the L-Shaped Method

Overview. We can rewrite Equation (1) as

$$\begin{aligned} z^* &= \min_x cx + \mathbb{E}h(x, s) \\ \text{s.t. } Ax &= b, x \geq 0, \end{aligned} \quad (2)$$

where

$$h(x, s) = \min_y \{q^s y : W^s y = r^s - T^s x, y \geq 0\}. \quad (\text{SUB}^s)$$

For ease of exposition, assume $\{\pi : \pi W^s \leq q^s\} \neq \emptyset$, $s = 1, 2, \dots, S$ and Equation (2) has *relatively complete recourse*, that is, for all $x \in X = \{Ax = b, x \geq 0\}$, (SUB^s) is feasible, for all $s = 1, 2, \dots, S$ and $X \neq \emptyset$ and compact. Let’s make the following observations: (i) for a fixed $x \in X$, Equation (2) decomposes into S subproblems given by (SUB^s) , $s = 1, 2, \dots, S$, (ii) it is well known that $\mathbb{E}h(x, s)$ is convex on X [11, Chapter 2, Proposition 13]. These observations constitute the heart of the primal decomposition algorithms for two-stage stochastic linear programs. In stochastic programming, this type of decomposition is referred to as the *L-shaped* method, owing to the shape of the block structure of a two-stage stochastic program [12]. However, the same algorithm with minor technical modifications is known as *Benders’ Decomposition* in integer programming [13] and as *Kelley’s cutting plane algorithm* in convex programming [14,15].

The idea of primal decomposition is to replace the *recourse function*, $\mathbb{E}h(x, s)$, by a lower approximating function. Since $\mathbb{E}h(x, s)$ is convex on X , such a lower approximation can be easily obtained via subgradients. The resulting problem is called the *master problem*, given by

$$\begin{aligned} \underline{z} &= \min_{x, \theta} cx + \theta \\ \text{s.t. } Ax &= b, x \geq 0, \\ G_i x + \theta &\geq g_i, i = 1, 2, \dots, I. \end{aligned} \quad (\text{MP}) \quad (3)$$

Here, θ is a variable representing the lower approximation of $\mathbb{E}h(x, s)$ and this lower approximation is given by the “cuts” in Equation (3). G_i are the cut gradients and g_i are the cut intercepts. The solution of the master problem provides two pieces of information. First, the optimal value of (MP) provides a lower bound on z^* , denoted by $\underline{z}$. Second, the optimal solution of the master problem, $\hat{x}$, yields a feasible ($A\hat{x} = b, \hat{x} \geq 0$) but typically suboptimal solution to Equation (2). This candidate solution, $\hat{x}$, is then passed to the subproblems (SUB^s) , $s = 1, 2, \dots, S$. Similar to the master problem, solution of the subproblems at $x = \hat{x}$ yields two pieces of information. First, the value of $\mathbb{E}h(\hat{x}, s)$ is obtained through $\sum_{s=1}^S p^s h(\hat{x}, s)$. This, together with the first stage cost at $\hat{x}$, that is, $\hat{z} = c\hat{x} + \mathbb{E}h(\hat{x}, s)$, provides an upper bound to z^* . Notice that since the lower approximation is sequentially refined throughout the algorithm, $\underline{z}$ is monotonically increasing. However, the upper bound, $\hat{z}$, can bounce as $\hat{x}$ changes. Therefore, we need to keep track of the best upper bound found so far, denoted as $\bar{z}$. The second piece of information that comes from solving the subproblems is a subgradient on $\mathbb{E}h(x, s)$. This information is then passed back to the relaxed master problem via a “cut” and the lower approximation is updated. With this more refined lower approximation, the master problem is solved again, a new candidate solution is obtained, and the algorithm continues in the same way until upper and lower bounds are sufficiently close, that is, $\bar{z} - \underline{z} \leq \text{toler} \cdot \max\{\|\bar{z}\|, \|\underline{z}\|\}$, where *toler* is a user specified tolerance.

To see how the subproblems yield a cut for the master problem, consider the simple

case of one scenario, $S = 1$. In this case, $\mathbb{E}h(x, s) = h(x, 1)$. The dual of (SUB¹) is $\max_{\pi} \{\pi(r^1 - T^1x) : \pi W^1 \leq q^1\}$. The feasible region of the dual problem is a polyhedron in standard form and is nonempty by our assumption, so, it has a finite number of extreme points, $\pi^1, \pi^2, \dots, \pi^L$. Furthermore, again by our assumption of relatively complete recourse, there exists an optimal solution at one these extreme points. Hence, we can equivalently write the dual as

$$h(x, 1) = \max_{l=1, \dots, L} \pi^l(r^1 - T^1x).$$

This is a piecewise linear convex function in x . There are an exponential number of extreme points; therefore, identifying all of them might not be efficient. The L-shaped method identifies only a subset of these that are needed to solve the problem. When (SUB¹) is solved at $\hat{x}$, this yields $\hat{\pi}$, one of the extreme dual points, which results in the cut

$$\theta \geq \hat{\pi}r^1 - \hat{\pi}T^1x. \quad (4)$$

Here, $-\hat{\pi}T^1$ is a subgradient of $h(x, 1)$ at $\hat{x}$ and Equation (4) is the subgradient inequality. The right-hand side of Equation (4) is equal to $\mathbb{E}h(\hat{x}, s)$ when evaluated at $x = \hat{x}$ and is less than or equal to $\mathbb{E}h(x, s)$ as we move away from $\hat{x}$. Relating Equation (4) to Equation (3), the cut gradient is $G = \hat{\pi}T^1$ and the cut intercept is $g = \hat{\pi}r^1$.

When there are a number of scenarios, that is, $S > 1$, using the fact that subgradient of $\mathbb{E}h(x, s)$ is equal to the expectation of the individual subgradients in our case [11, Chapter 2, Proposition 13], we can obtain a cut with

$$G_i = \sum_{s=1}^S p^s \pi_i^s T^s, \text{ and } g_i = \sum_{s=1}^S p^s \pi_i^s r^s, \quad (5)$$

where $\pi_i^s, s = 1, 2, \dots, S$ are the optimal duals obtained from (SUB^s)'s at iteration i of the algorithm. Cuts of the form of Equation (3) are called the *optimality cuts*. If we relax the assumption of relatively complete recourse, it is possible to obtain $\hat{x} \in X$ when (MP) is solved, which causes infeasibility in at least

one of the subproblems. Such a first stage decision must be eliminated. This can be done via the so-called *feasibility cuts*. Feasibility cuts are obtained in a similar fashion to Equations (4) and (5) but using the Phase-I problem corresponding to (SUB^s)'s. For brevity, we skip the details and refer the readers to Birge and Louveaux [2] and Ruszczyński and Shapiro [11].

Enhancements and Extensions. We presented a basic version of the L-shaped method above with only optimality cuts and what is called a *single cut version*. A *multicut* version, analyzed by Birge and Louveaux [16], replaces θ in (MP) by $\sum_{s=1}^S p^s \theta^s$, where θ^s is a lower approximation of $h(x, s)$ for each $s = 1, 2, \dots, S$. In this case, instead of the aggregate cuts in Equation (3), S cuts of the form of Equation (4) are generated from each subproblem and added to the master problem. This can speed up the convergence of the L-shaped method. However, it can also result in a larger master problem, especially in later iterations. Variations in between single and multicut versions are possible, where several scenarios can be bundled together to form a cut for this group.

In the early iterations of the L-shaped method, solutions can oscillate wildly, slowing convergence. The *regularized decomposition* of Ruszczyński [17] and Ruszczyński and Świetanowski [18] adds a quadratic regularizing term to the objective function of the master problem that encourages the new solution to remain close to the current solution. This controls the size of the steps taken by the algorithm and also limits the number of cuts that need to be stored in the master problem. As a result, significant savings in total computation time can be achieved, even though a quadratic master problem needs to be solved. In an effort to speed up convergence, *trust regions* similarly aim to control the size of the steps taken by the algorithm. Trust regions are constraints in the master problem that restrict the new solution to be within a region close to the current solution. Typically, l_1 or l_∞ norms are used as these can be represented as linear constraints. Successful implementations of trust regions in stochastic programming can be

found in Keller and Bayraksan [19], Linderoth and Wright [20], and Santoso *et al.* [21]. Finally, L-shaped method is amenable to *parallel* implementation [20,22].

The L-shaped method has been extended to work for a larger class of stochastic programs. For multistage stochastic programs, *nested L-shaped* or *nested decomposition* method [23,24] decomposes multistage stochastic programs by stage and works in a similar fashion. In the forward pass of the algorithm, candidate solutions for the future stages are passed on, and in the backward pass of the algorithm, cuts are provided to the previous stages. When the first stage variables are integer and the second stage is continuous, L-shaped method works exactly like the Benders decomposition. However, when there are integrality restrictions in the second stage, the recourse function is often discontinuous and nonconvex in x and this complicates the L-shaped method. The *integer L-shaped* method of Laporte and Louveaux [25] overcomes this difficulty by providing cuts that are linear in x in the case of pure binary first stage variables. The second stage (mixed) integer programs need to be solved to optimality to obtain these cuts, which can be computationally undesirable. Also, these cuts are known to be weak. The *disjunctive decomposition* method of Sen and Hingle [26] expands on the L-shaped method and allows efficient solution of the subproblems as linear programming (LP) relaxations. The LP relaxations are sequentially refined throughout the algorithm by the use of disjunctive cuts that eliminate fractional solutions in the second stage. For computational experience an extensions on disjunctive decomposition see, Ntamo [27], Ntamo and Sen [28,29], and Sen and Sherali [30].

Dual Decomposition

Let us again rewrite Equation (1), this time by duplicating the first stage variables for each scenario. The resulting equivalent reformulation of Equation (1) is

$$\min_{\substack{x^1, \dots, x^S, \\ y^1, \dots, y^S}} \sum_{s=1}^S p^s (cx^s + q^s y^s)$$

$$\text{s.t. } Ax^s = b, \quad s = 1, 2, \dots, S, \quad (6)$$

$$T^s x^s + W^s y^s = r^s, \quad s = 1, 2, \dots, S, \quad (7)$$

$$x^s \geq 0, y^s \geq 0, \quad s = 1, 2, \dots, S, \quad (8)$$

$$x^1 = x^2 = \dots = x^S. \quad (9)$$

Constraints (9) are called the *nonanticipativity constraints*, which force the first stage variables to be identical across scenarios. Nonanticipativity constraints can be represented in different ways and Equation (9) is one possible way. The idea of the dual decomposition methods is to relax the nonanticipativity constraints and solve the resulting Lagrangian dual problem. In the linear case, this can be done by the classic Dantzig–Wolfe decomposition [31]. Let $Gx = 0$ represent the nonanticipativity constraints. For example, when there are two scenarios ($S=2$), $G = [I; -I]$, where I is an identity matrix of size d_x . Given Lagrange multipliers λ , the Lagrangian is

$$\mathcal{L}(x, y, \lambda) = \sum_{s=1}^S p^s (cx^s + q^s y^s) + \sum_{s=1}^S \langle \lambda, G^s x^s \rangle. \quad (10)$$

The relaxed problem $D(\lambda) = \min_{x,y} \{\mathcal{L}(x, y, \lambda)\}$: Equations (6)–(8) decomposes into S separable scenario subproblems. Each of the resulting subproblems is a two-stage stochastic program with exactly one scenario, s , and decisions x^s and y^s . The Lagrangian dual

$$\max_{\lambda} D(\lambda)$$

can then be solved by standard optimization techniques. For example, it is well known that $D(\lambda)$ is concave in λ and a master problem can be created that gives an upper approximation to $D(\lambda)$, whose solution yields a $\hat{\lambda}$ and an upper bound, $\bar{z}$. $\hat{\lambda}$ is then passed on the subproblems, that is, $D(\hat{\lambda}) = \min_{x,y} \{\mathcal{L}(x, y, \hat{\lambda})\}$: Equations (6)–(8) is solved by solving the S separable subproblems. This in turn provides a better upper approximation by providing a “cut” to the master problem, again by the use of subgradient inequality—but for a concave

function—and a possible lower bound. Primal solutions, x , are also updated and the best lower bound found so far is stored as $\underline{z}$. The algorithm continues until the upper and lower bounds are sufficiently close, that is, $\bar{z} - \underline{z} \leq \text{toler} \cdot \max\{|\bar{z}|, |\underline{z}|\}$, where toler is a user-specified tolerance.

We note a difference between the L-shaped method and the dual decomposition method. In the L-shaped method, the master problem decisions are x and θ , which represents the lower approximation of $\mathbb{E}h(x, s)$, and in the dual decomposition, the master problem decisions are λ and θ , which, this time, represents the upper approximation of $D(\lambda)$. The size of λ grows as the number of scenarios grow but the size of x remains the same. Therefore, solving the dual master can become harder as S grows. Nevertheless, dual decomposition methods have been successfully applied to multistage stochastic programs, especially when the subproblems have a special structure, enabling efficient solution.

In particular, *augmented Lagrangian* methods have proven useful in multistage stochastic programs. These augment the Lagrangian equation (10) with a quadratic term that penalizes deviations in the nonanticipativity constraints. Two of the well-known dual decomposition methods for stochastic programs, the *progressive hedging* algorithm of Rockafeller and Wets [32] and the *scenario decomposition* method of Mulvey and Ruszczyński [33], are augmented Lagrangian methods. They differ in the way the nonanticipativity constraints are written, the way the subproblems are solved, and the way the Lagrange multipliers are updated. For stochastic integer programs, a duality gap exists, so, a Lagrangian dual method can be combined with branch and bound [34]. Progressive hedging has been applied to mixed integer multistage stochastic programs [35–37] without convergence guarantees due to loss of convexity but empirical convergence has been observed. For a computational comparison of nested L-shaped and an augmented Lagrangian implementation on a class of multistage stochastic mean-variance portfolio problems, see Parpas and Rustem [38].

APPROXIMATE SOLUTION METHODS

As d_ξ , the dimension of the random vector, grows stochastic programs can quickly become intractable. For instance, for discrete random vectors the problem size can grow exponentially in this dimension. For continuous random vectors, taking expectations—even for a fixed x —gets very difficult as the dimension of the integral grows. Furthermore, the size of the multistage stochastic programs grows exponentially in the number of stages. Some of these approximations exploit the structural properties of the underlying stochastic programs—such as the bounds based on convexity of the recourse function—and some are general, for example, Monte Carlo sampling-based approximations. Once a computationally tractable approximation of (SP) is formed, the idea of approximate solution methods is to sequentially refine this approximation until a solution of desired quality is obtained. Sometimes, the tractable approximation is used within one of the exact solution methods described above, providing estimates of the expectations and subgradients required throughout the algorithm. Approximate solution methods mainly differ in the way the approximations are formed, the way refinements to these approximations are made, and if they are used internally to other solution procedures or not. We review two common types of approximations used for solving stochastic programs below.

Monte Carlo Sampling-Based Approximations

Let $\tilde{\xi}^1, \tilde{\xi}^2, \dots, \tilde{\xi}^n$ be independent and identically distributed (i.i.d.) random variables as $\tilde{\xi}$. A sampling approximation of Equation (1) or Equation (2) is

$$z_n^* = \min_{x \in X} cx + \frac{1}{n} \sum_{i=1}^n h(x, \tilde{\xi}^i). \quad (\text{SP}_n)$$

This is referred to as a *sample average approximation* (SAA). Let x_n^* denote an optimal solution to (SP_n) . The pair (z_n^*, x_n^*) provides statistical estimators of the optimal value and optimal solution of (SP), respectively. Monte Carlo sampling-based

approximations are typically justified by providing conditions under which z_n^* converges to z^* and the limit points of x_n^* solve (SP) [39–42]. There is also work on the rate of convergence of these estimators. For certain classes of stochastic programs such as stochastic integer programs with integer first stage, and for two-stage stochastic linear programs with discrete distributions, the rate of convergence can be exponential [43,44]. While the above uses i.i.d. sampling, sampling can be done in different ways, for instance, stratified sampling or antithetic variates can be used to reduce variance. For the analysis and computational experiments with alternate sampling methods and variance reduction techniques in the context of stochastic programming see [45–48].

(SP_n) is essentially the same as Equation (1) with $S = n$ and $p^1 = p^2 = \dots = p^n = \frac{1}{n}$. Of course, in the case of finite Ξ , when S is prohibitively large to allow an exact solution method, sample size can be chosen such that $n \ll S$ to achieve tractability. Then, (SP_n) can be solved by any of the exact solution methods described above. Such an approach is referred to as *external sampling*. We note that this is not an approximate “solution method” but provides approximations, (z_n^*, x_n^*) , that are statistical in nature. Sampling is done externally to construct an instance of (SP_n) and the resulting problem is solved via an exact solution method. For (SP) with $K \geq 1$, such as stochastic programs with probabilistic constraints, feasibility of the solutions found by SAA becomes an issue. Sample sizes that guarantee feasibility with a certain confidence level have been analyzed for such problems [49,50].

Sampling approximations can also be used *internal* to an exact solution method. For example, sampling can be done within a branch and bound algorithm [51]. We collectively refer to these approximate solution methods as *internal sampling* methods. One set of such algorithms are rooted in the L-shaped method. The *stochastic decomposition* method of Hige and Sen [52] uses sampling-based cutting planes within the L-shaped method. Pereira and Pinto [53] provide an extension in the multistage setting and Infanger [54] and Dantzig and Infanger

[45] embed importance sampling within the L-shaped method.

Another class of sampling-based solution methods are the stochastic versions of steepest descent where the (sub)gradients used within the algorithm are replaced by their sampling-based estimators. *Stochastic approximation* (SA) [55] and the *stochastic quasi-gradient* (SQG) [56] belong to this category. They are rooted in the Robbins and Monro [57] and Kiefer and Wolfowitz [58] stochastic approximation methods, where the former uses unbiased estimators of the (sub)gradients and the latter uses finite differences to estimate the (sub)gradients. One advantage of these methods is that they have the potential to handle decision-dependent stochasticity; however, they do not take full advantage of the special structures found in many stochastic programs. They can also be sensitive to the step sizes used and can have slower convergence. Recent modifications to the SA method use longer step sizes to improve convergence and averages solutions to reduce noise. The resulting robust mirror descent SA has promising numerical performance [59].

Bounding Approximations

Another way to handle the difficult expectations in (SP) is by replacing them with bounds that are easier to calculate. These bounds can be embedded in a solution method that sequentially refines them. Bounds in stochastic programming can be derived via: (i) appropriate approximations of the distribution of ξ , or (ii) functional approximations that replace the complicated expectations with an easy function to calculate, and typically for multistage problems by (iii) aggregating the time stages and appropriately changing the information structure and the timing of the data revelation. For details on bounds of the third type, we refer the readers to [60–63]. Bounds for stochastic programs with probabilistic constraints can be obtained by replacing the probabilistic constraint(s) with expressions using probability inequalities, such as generalizations of Chebyshev’s inequality. These can be viewed as bounds of type two above. For details, we refer the readers to Section 9.4 of Birge and

Louveaux [2] for earlier developments and the article by Nemirovski and Shapiro [64] for more recent developments in this area.

Bounds of the first type, that is, that approximate the probability distribution, have been used most often in an algorithmic setting. These include bounds based on Jensen's [65] and Edmundson-Madansky (E-M) [66–68] inequalities. Bounds obtained through Jensen's inequality replace the distribution of $\tilde{\xi}$ by a single point, $\mathbb{E}\tilde{\xi}$, the expected value of $\tilde{\xi}$. Then, if $h(x, \tilde{\xi})$ is convex on Ξ , a lower bound is obtained by $h(x, \mathbb{E}\tilde{\xi}) \leq \mathbb{E}h(x, \tilde{\xi})$. Calculating $h(x, \mathbb{E}\tilde{\xi})$ for a fixed x is quite easy; it requires only one function evaluation at $\mathbb{E}\tilde{\xi}$. Bounds obtained through E-M inequality, on the other hand, replace the distribution of $\tilde{\xi}$ with an extremal distribution that puts mass on the extreme points of the supports of the elements of $\tilde{\xi}$ (assuming Ξ is bounded). Under convexity of $h(x, \tilde{\xi})$ on Ξ , this provides an upper bound. Since $h(x, \tilde{\xi})$ has to be evaluated at the extreme points of Ξ , the computational effort grows exponentially in $d_{\tilde{\xi}}$. Bounds based on Jensen's and E-M inequalities have been improved over the years to allow for correlations, use of more distributional information such as second moments, and also to allow for more general, possibly unbounded Ξ [69–72]. An alternative to the E-M bound is the piecewise linear bound [73–75], which replaces $\mathbb{E}h(x, \tilde{\xi})$ by a sum of $d_{\tilde{\xi}}$ one-dimensional expectations. Thus, the computational effort grows linearly in $d_{\tilde{\xi}}$. These are bounds of the second type, that is, they are based on functional approximations. Note that bounds based on functional approximations and extensions of bounds based on Jensen's and E-M inequalities can be formed by *generalized moment problems*, which have been first explored in the context of stochastic programming by Dupačová [76].

Bounds can be used in an algorithmic way to find approximate solutions to (SP). These methods are referred to as *sequential approximation methods* [77,78]. They sequentially partition the support of the random vector Ξ and form upper and lower bounds on the conditional expectations of each partition. As the partitions become more refined, bounds become tighter and

the method terminates when upper and lower bounds are sufficiently close to each other. Another way to refine the bounds is to tighten the generalized moment problems.

Convergence and Quality of Approximate Solutions

Convergence of approximations is a desired property. While convergence can be shown in a variety of ways, *epiconvergence* provides an appropriate framework for approximations of optimization problems. A sequence of functions g_v is said to epiconverge to g if the epigraphs of g_v converge to that of g . The epigraph of g is defined as the set $\text{epi } g = \{(x, \alpha) : \alpha \geq g(x)\}$. Epiconvergence is convenient for optimization because of the property that if $\hat{x}$ is an accumulation point of $x_v^* \in \arg \min g_v(x)$, then it solves the original problem, that is, $\hat{x} \in \arg \min g(x)$. For instance, in (SP_n) , $g_v(x) = \mathbb{E}_n \bar{f}_0(x, \tilde{\xi})$ and $g(x) = \mathbb{E} \bar{f}_0(x, \tilde{\xi})$, where $\bar{f}_0$ is similar to f_0 but captures the feasibility constraints by taking value $+\infty$ when x is not a feasible solution, and $\mathbb{E}_n$ is the expectation taken with respect to the empirical measure $\mathbb{P}_n = \sum_{i=1}^n \frac{1}{n} \delta_{\tilde{\xi}^i}$, where $\delta_{\tilde{\xi}^i}$ denotes the unit mass on $\tilde{\xi}^i$. A similar setup is possible, for example, when a bounding approximation replaces the probability distribution with $\mathbb{P}_v$. Then, if $\mathbb{P}_v$ converges weakly to $\mathbb{P}$ almost surely, and f satisfies certain regularity conditions, we can achieve epiconvergence. For a comprehensive treatment of epiconvergence see Rockafellar and Wets [79], for its implications on approximate optimization problems see Kall [80] and for its use in stochastic programming see Birge and Wets [77].

While convergence is a desired property, in practice, given finite computational power, approximations of (SP) yield only approximate solutions. Thus, the quality of the obtained solutions needs to be determined. Such quality statements can sometimes be made within an approximate solution method, for example, by providing the difference between upper and lower bounds. When such a quality statement is not available, Monte Carlo sampling-based methods can be used to provide point and interval estimators of the optimality gap of a candidate solution

found by any method. Such procedures for (SP) with $K = 0$ under fairly general conditions have been developed in Mak *et al.* [81], see also the tutorial by Bayraksan and Morton [82]. Note that these statistical estimators can be used in conjunction with any approximate method that eventually produces solutions that solve (SP) to design an approximate solution procedure. For instance, external or internal sampling methods can generate x_n^* using sample size n . Then, a statistical estimator of its optimality gap can be generated. If the optimality gap is sufficiently small, then this solution provides a high-quality solution with a desired confidence level. Otherwise, the sample size is increased. For rules to increase sample sizes and to stop such a *sequential sampling procedure* see Bayraksan and Morton [83].

Solution quality for (SP) with $K \geq 1$ involves two components: first, to ensure that the approximate solution is feasible (depending on the type of approximation) and second, to provide bounds on the optimal value. If approximation is done via Monte Carlo sampling, then, as mentioned above, feasibility becomes an issue. For bounding approximations, feasibility can be automatically satisfied as the constraints that replace, for instance, a probabilistic constraint guarantee that this constraint is satisfied. For methods that provide probabilistic statements on the feasibility of approximate solutions and the objective values for this class of problems, see [50,64,84].

CONCLUDING REMARKS

This article provides an overview of solution methods for stochastic programs. In particular, decomposition-based solution techniques are discussed. Two common classes of approximate solution methods, one rooted in Monte Carlo sampling-based approximations and the other in deterministically valid bounding approximations are introduced. Convergence and solution quality of approximate solutions are discussed.

As this is intended as an overview article, and the topic is too extensive to cover in detail, for more details on algorithmic approaches to different classes of

stochastic programs, we refer the reader to the section titled “Optimization under Uncertainty” of this encyclopedia. In our treatment of the subject, we mainly focused on stochastic programs with recourse, so, for solution methods for stochastic programs with probabilistic constraints. We note that discretization can be done in other ways besides Monte Carlo sampling, for details on different scenario generation and reduction techniques see the article titled **Scenario Generation** in this encyclopedia. Finally, for information about stochastic programming software. For a deeper understanding of the methods discussed above, see textbooks Birge and Louveaux [2] and Shapiro *et al.* [85] and also the handbook [11]. Interested readers can also look at the stochastic programming community website, www.stoprog.org, which contains a wealth of information including introductory materials. A searchable online bibliography on stochastic programming can be found at <http://www.eco.rug.nl/mally/spbib.html>.

We end by noting that developing efficient solution methods for stochastic programs is an exciting and ever growing area of research. Some of the current research includes solving different classes of (SP), such as multistage stochastic mixed integer programs, possibly with nonlinear constraints/objectives, and stochastic programs with stochastic dominance and probabilistic constraints. Another challenge is to develop continuous versions of stochastic programs and enable their solutions. For instance, stochastic programs with (stochastic) differential equations still await modeling and efficient solution techniques.
